1 Introduction	7
1.1 Three Levels for Thinking About Code	9
1.2 Functional Programming	11
1.2.1 What Functional Programming Is	11
1.2.2 What Functional Programming Isn't	13
1.2.3 Why It Matters	15
1.2.4 The Evidence for Functional Programming	16
1.2.5 Final Words	17

I Theory	19
2 Algebraic Data Types	21
2.1 Building Algebraic Data Types	22
2.1.1 Sums and Products	22
2.1.2 Closed Worlds	23
2.2 Algebraic Data Types in Scala	23
2.2.1 Algebraic Data Types in Scala 3	24
2.2.2 Algebraic Data Types in Scala 2	25
2.2.3 Examples	26
2.2.4 Representing ADTs in Scala 3	28
2.3 Structural Recursion	29
2.3.1 Pattern Matching	29
2.3.2 The Recursion in Structural Recursion	30
2.3.3 Exhaustivity Checking	35
2.3.4 Dynamic Dispatch	36
2.3.5 Folds as Structural Recursions	37
2.4 Structural Corecursion	40
2.4.1 Unfolds as Structural Corecursion	43
2.5 Applications of Algebraic Data Types	49
2.6 The Algebra of Algebraic Data Types	50
2.7 Conclusions	53
3 Type Classes	57
3.1 Anatomy of a Type Class	58
3.1.1 The Type Class	58

3.1.2	Type Class Instances	59
3.1.3	Type Class Use	59
3.2	Working with Implicits	62
3.2.1	Packaging Implicits	62
3.2.2	Implicit Scope	62
3.2.3	Recursive Implicit Resolution	64
3.3	Exercise: Printable Library	67
3.4	Meet Cats	69
3.4.1	Importing Type Classes	69
3.4.2	Importing Default Instances	70
3.4.3	Importing Interface Syntax	71
3.4.4	Importing All The Things!	71
3.4.5	Defining Custom Instances	72
3.4.6	Exercise: Cat Show	73
3.5	Example: Eq	73
3.5.1	Equality, Liberty, and Fraternity	73
3.5.2	Comparing Ints	74
3.5.3	Comparing Options	75
3.5.4	Comparing Custom Types	76
3.5.5	Exercise: Equality, Liberty, and Felinity	77
3.6	Controlling Instance Selection	77
3.6.1	Variance	78
3.7	Summary	81

4 Monoids and Semigroups	83
4.1 Definition of a Monoid	85
4.2 Definition of a Semigroup	86
4.3 Exercise: The Truth About Monoids	87
4.4 Exercise: All Set for Monoids	88
4.5 Monoids in Cats	88
4.5.1 The Monoid Type Class	88
4.5.2 Monoid Instances	89
4.5.3 Monoid Syntax	90
4.5.4 Exercise: Adding All The Things	91
4.6 Applications of Monoids	91
4.6.1 Big Data	92
4.6.2 Distributed Systems	92
4.6.3 Monoids in the Small	93
4.7 Summary	93
5 Functors	95
5.1 Examples of Functors	95
5.2 More Examples of Functors	97
5.3 Definition of a Functor	102
5.4 Aside: Higher Kinds and Type Constructors	103
5.5 Functors in Cats	105
5.5.1 The Functor Type Class and Instances	105
5.5.2 Functor Syntax	106
5.5.3 Instances for Custom Types	108
5.5.4 Exercise: Branching out with Functors	109

5.6	Contravariant and Invariant Functors	109
5.6.1	Contravariant Functors and the <i>contramap</i> Method	110
5.6.2	Invariant functors and the <i>imap</i> method	113
5.7	Contravariant and Invariant in Cats	116
5.7.1	Contravariant in Cats	116
5.7.2	Invariant in Cats	117
5.8	Aside: Partial Unification	118
5.8.1	Limitations of Partial Unification	120
5.9	Summary	122
6	Monads	125
6.1	What is a Monad?	125
6.1.1	Definition of a Monad	130
6.1.2	Exercise: Getting Func-y	131
6.2	Monads in Cats	132
6.2.1	The Monad Type Class	132
6.2.2	Default Instances	133
6.2.3	Monad Syntax	134
6.3	The Identity Monad	136
6.3.1	Exercise: Monadic Secret Identities	138
6.4	Either	138
6.4.1	Left and Right Bias	139
6.4.2	Creating Instances	140
6.4.3	Transforming Eithers	142
6.4.4	Error Handling	143
6.4.5	Exercise: What is Best?	145

6.5	Aside: Error Handling and MonadError	145
6.5.1	The MonadError Type Class	146
6.5.2	Raising and Handling Errors	147
6.5.3	Instances of MonadError	148
6.5.4	Exercise: Abstracting	149
6.6	The Eval Monad	150
6.6.1	Eager, Lazy, Memoized, Oh My!	150
6.6.2	Eval's Models of Evaluation	152
6.6.3	Eval as a Monad	154
6.6.4	Trampolining and <i>Eval.defer</i>	155
6.6.5	Exercise: Safer Folding using Eval	157
6.7	The Writer Monad	157
6.7.1	Creating and Unpacking Writers	158
6.7.2	Composing and Transforming Writers	160
6.7.3	Exercise: Show Your Working	162
6.8	The Reader Monad	164
6.8.1	Creating and Unpacking Readers	164
6.8.2	Composing Readers	165
6.8.3	Exercise: Hacking on Readers	166
6.8.4	When to Use Readers?	167
6.9	The State Monad	168
6.9.1	Creating and Unpacking State	168
6.9.2	Composing and Transforming State	169
6.9.3	Exercise: Post-Order Calculator	172
6.10	Defining Custom Monads	175

6.10.1	Exercise: Branching out Further with Monads	177
6.11	Summary	178
7	Monad Transformers	181
7.1	Exercise: Composing Monads	182
7.2	A Transformative Example	183
7.3	Monad Transformers in Cats	184
7.3.1	The Monad Transformer Classes	185
7.3.2	Building Monad Stacks	185
7.3.3	Constructing and Unpacking Instances	188
7.3.4	Default Instances	190
7.3.5	Usage Patterns	190
7.4	Exercise: Monads: Transform and Roll Out	192
7.5	Summary	193
8	Semigroupal and Applicative	195
8.1	Semigroupal	196
8.1.1	Joining Two Contexts	197
8.1.2	Joining Three or More Contexts	198
8.1.3	Semigroupal Laws	198
8.2	Apply Syntax	198
8.2.1	Fancy Functors and Apply Syntax	201
8.3	Semigroupal Applied to Different Types	202
8.3.1	Semigroupal Applied to Monads	204
8.4	Parallel	205
8.5	Apply and Applicative	209

8.5.1	The Hierarchy of Sequencing Type Classes	210
8.6	Summary	212
9	Foldable and Traverse	213
9.1	Foldable	213
9.1.1	Folds and Folding	214
9.1.2	Exercise: Reflecting on Folds	215
9.1.3	Exercise: Scaf-fold-ing Other Methods	215
9.1.4	Foldable in Cats	215
9.2	Traverse	220
9.2.1	Traversing with Futures	220
9.2.2	Traversing with Applicatives	223
9.2.3	Traverse in Cats	226
9.3	Summary	227
II	Case Studies	229
10	Case Study: Testing Asynchronous Code	231
10.1	Abstracting over Type Constructors	233
10.2	Abstracting over Monads	234
10.3	Summary	235
11	Case Study: Map-Reduce	237
11.1	Parallelizing <i>map</i> and <i>fold</i>	237
11.2	Implementing <i>foldMap</i>	239
11.3	Parallelising <i>foldMap</i>	241
11.3.1	<i>Futures</i> , Thread Pools, and ExecutionContexts	241

11.3.2 Dividing Work	244
11.3.3 Implementing <i>parallelFoldMap</i>	245
11.3.4 <i>parallelFoldMap</i> with more Cats	245
11.4 Summary	246
12 Case Study: Data Validation	247
12.1 Sketching the Library Structure	248
12.2 The Check Datatype	251
12.3 Basic Combinators	252
12.4 Transforming Data	253
12.4.1 Predicates	254
12.4.2 Checks	256
12.4.3 Recap	258
12.5 Kleislis	259
12.6 Summary	263
13 Case Study: CRDTs	265
13.1 Eventual Consistency	265
13.2 The GCounter	266
13.2.1 Simple Counters	266
13.2.2 GCounters	268
13.2.3 Exercise: GCounter Implementation	269
13.3 Generalisation	270
13.3.1 Implementation	272
13.3.2 Exercise: BoundedSemiLattice Instances	273
13.3.3 Exercise: Generic GCounter	273

13.4 Abstracting GCounter to a Type Class	273
13.5 Abstracting a Key Value Store	275
13.6 Summary	277
III Solutions to Exercises	279
A Solutions for: Algebraic Data Types	281
A.1 Iterate	281
A.2 Map	282
A.3 Identities	282
A.4 Identities Part 2	282
B Solutions for: Type Classes	283
B.1 Printable Library	283
B.2 Printable Library Part 2	284
B.3 Printable Library Part 3	285
B.4 Cat Show	286
B.5 Equality, Liberty, and Felinity	287
C Solutions for: Monoids and Semigroups	289
C.1 The Truth About Monoids	289
C.2 All Set for Monoids	290
C.3 Adding All The Things	291
C.4 Adding All The Things Part 2	292
C.5 Adding All The Things Part 3	293

D Solutions for: Functors	295
D.1 Branching out with Functors	295
D.2 Showing off with Contramap	296
D.3 Showing off with Contramap Part 2	297
D.4 Transformative Thinking with imap	298
D.5 Transformative Thinking with imap Part 2	298
D.6 Transformative Thinking with imap Part 3	298
E Solutions for: Monads	301
E.1 Getting Func-y	301
E.2 Monadic Secret Identities	302
E.3 What is Best?	303
E.4 Abstracting	304
E.5 Safer Folding using Eval	304
E.6 Show Your Working	305
E.7 Hacking on Readers	307
E.8 Hacking on Readers Part 2	307
E.9 Hacking on Readers Part 3	308
E.10 Post-Order Calculator	308
E.11 Post-Order Calculator Part 2	309
E.12 Post-Order Calculator Part 3	310
E.13 Branching out Further with Monads	310
F Solutions for: Monad Transformers	315
F.1 Monads: Transform and Roll Out	315
F.2 Monads: Transform and Roll Out Part 2	315

F.3	Monads: Transform and Roll Out Part 3	316
F.4	Monads: Transform and Roll Out Part 4	316
G	Solutions for: Semigroupal and Applicative	319
G.1	The Product of Lists	319
G.2	Parallel List	320

L.3 Generic GCounter	359
L.4 Abstracting GCounter to a Type Class	359
L.5 Abstracting a Key Value Store	360

Preface

The aims of this book are two-fold: to introduce monads, functors, and other functional programming patterns as a way to structure program design, and to explain how these concepts are implemented in [Cats](#).

Monads, and related concepts, are the functional programming equivalent of object-oriented design patterns—architectural building blocks that turn up over and over again in code. They differ from object-oriented patterns in two main ways:

- they are formally, and thus precisely, defined; and
- they are extremely (extremely) general.

This generality means they can be difficult to understand. Everyone finds abstraction difficult. However, it is generality that allows concepts like monads to be applied in such a wide variety of situations.

In this book we aim to show the concepts in a number of different ways, to help you build a mental model of how they work and where they are appropriate. We have extended case studies, a simple graphical notation, many smaller examples, and of course the mathematical definitions. Between them we hope you'll find something that works for you.

Ok, let's get started!

Versions

This book is written for Scala 3.3.0 and Cats 2.9.0. Here is a minimal `build.sbt` containing the relevant dependencies and settings¹:

```
scalaVersion := "3.3.0"

libraryDependencies +=
  "org.typelevel" %% "cats-core" % "2.9.0"

scalacOptions ++= Seq(
  "-Xfatal-warnings"
)
```

Template Projects

For convenience, we have created a Giter8 template to get you started. To clone the template type the following:

```
$ sbt new scalawithcats/cats-seed.g8
```

This will generate a sandbox project with Cats as a dependency. See the generated `README.md` for instructions on how to run the sample code and/or start an interactive Scala console.

The `cats-seed` template is very minimal. If you'd prefer a more batteries-included starting point, check out Typelevel's `sbt-catalysts` template:

```
$ sbt new typelevel/sbt-catalysts.g8
```

This will generate a project with a suite of library dependencies and compiler plugins, together with templates for unit tests and documentation. See the project pages for [catalysts](#) and [sbt-catalysts](#) for more information.

¹We assume you are using SBT 1.0.0 or newer.

Conventions Used in This Book

This book contains a lot of technical information and program code. We use the following typographical conventions to reduce ambiguity and highlight important concepts:

Typographical Conventions

New terms and phrases are introduced in *italics*. After their initial introduction they are written in normal roman font.

Terms from program code, filenames, and file contents, are written in monospace font. Note that we do not distinguish between singular and plural forms. For example, we might write `String` or `Strings` to refer to `java.lang.String`.

References to external resources are written as [hyperlinks](#). References to API documentation are written using a combination of hyperlinks and monospace font, for example: [scala.Option](#).

Source Code

Source code blocks are written as follows. Syntax is highlighted appropriately where applicable:

```
object MyApp extends App {  
    println("Hello world!") // Print a fine message to the user!  
}
```

Most code passes through `mdoc` to ensure it compiles. `mdoc` uses the Scala console behind the scenes, so we sometimes show console-style output as comments:

```
"Hello Cats!".toUpperCase  
// res0: String = "HELLO CATS!"
```

Callout Boxes

We use two types of *callout box* to highlight particular content:

Tip callouts indicate handy summaries, recipes, or best practices.

Advanced callouts provide additional information on corner cases or underlying mechanisms. Feel free to skip these on your first read-through—come back to them later for extra information.

Acknowledgements

We'd like to thank our colleagues at Inner Product and Underscore, our friends at Typelevel, and everyone who helped contribute to this book. Special thanks to Jenny Clements for her fantastic artwork and Richard Dallaway for his proof reading expertise. Here is an alphabetical list of contributors:

Alessandro Marrella, Cody Koeninger, Connie Chen, Conor Fennell, Dani Rey, Daniela Sfregola, Danielle Ashley, David Castillo, David Piggott, Denis Zjukow, Dennis Hunziker, Deokhwan Kim, Edd Steel, Eduardo Obando Boschini, Eugene Yushin, Evgeny Veretennikov, Francis Devereux, Ghislain Vaillant, Gregor Ihmor, Henk-Jan Meijer, Janne Pelkonen, Jason Scott, Javier Arrieta, Jenny Clements, Jérémie Jost, Joachim Hofer, Jonathon Ferguson, Lance Paine, Leif Wickland, Itbs, Marc Prud'hommeaux, Martin Carolan, mizuno, Mr-SD, Narayan Iyer, Niccolo' Paravanti, niqdev, Noor Nashid, Pablo Francisco Pérez Hidalgo, Paweł Jurczenko, Phil Derome, Philip Schwarz, Riccardo Sirigu, Richard Dallaway, Robert Stoll, Rodney Jacobsen, Rodrigo B. de Oliveira, Rud Wangrungarun, Seoh Char, Sergio Magnacco, Shohei Shimomura, Tim McIver, Toby Weston, Victor Osolovskiy, and Yinka Erinle.

If you spot an error or potential improvement, please raise an issue or submit a PR on the book's [Github page](#).

Backers

We'd also like to extend very special thanks to our backers—fine people who helped fund the development of the book by buying a copy before we released it as open source. This book wouldn't exist without you:

A battle-hardened technologist, Aaron Pritzlaff, Abhishek Srivastava, Aleksey "Daron" Terekhin, Algolia, Allen George (@allenageorge), Andrew Johnson, Andrew Kerr, Andy Dwelly, Anler, anthony@dribble.ai, Aravindh Sridaran, Araxis Ltd, ArtemK, Arthur Kushka (@arhelmus), Artur Zhurat, Arturas Smorgun, Attila Mravik, Axel Gschaider, Bamboo Le, bamine, Barry Kern, Ben Darfler (@bdarfler), Ben Letton, Benjamin Neil, Benoit Hericher, Bernt Andreas Langøien, Bill Leck, Blaze K, Boniface Kabaso, Brian Wongchaowart, Bryan Dragon, @cannedprimates, Ceschiatti (@6qat), Chris Gojlo, Chris Phelps, @CliffRedmond, Cody Koeninger, Constantin Gonciulea, Dadepo Aderemi, Damir Vandic, Damon Rolfs, Dan Todor, Daniel Arndt, Daniela Sfregola, David Greco, David Poltorak, Dennis Hunziker, Dennis Vriend, Derek Morr, Dimitrios Liapis, Don McNamara, Doug Clinton, Doug Lindholm (dlindhol), Edgar Mueller, Edward J Renauer Jr, Emiliano Martinez, esthom, Etienne Peiniau, Fede Silva, Filipe Azevedo, Franck Rasolo, Gary Coady, George Ball, Gerald Loeffler, Integrational, Giles Taylor, Guilherme Dantas (@gamsd), Harish Hurchurn, Hisham Ismail, Iurii Susuk, Ivan (SkyWriter) Kasatenko, Ivano Pagano, Jacob Baumbach, James Morris, Jan Vincent Liwanag, Javier Gonzalez, Jeff Gentry, Joel Chovanec, Jon Bates, Jorge Aliss (@jaliss), Juan Macias (@1macias1), Juan Ortega, Juan Pablo Romero Méndez, Jungsun Kim, Kaushik Chakraborty (@kaychaks), Keith Mannock, Ken Hoffman, Kevin Esler, Kevin Kyro, kbillies, Klaus Rehm, Kostas Skourtis, Lance Linder, Liang, Guang Hua, Loïc Girault, Luke Tebbs, Makis A, Malcolm Robbins, Mansur Ashraf (@mansur_ashraf), Marcel Lüthi, Marek Prochera @hicolour, Marianudo (Mariano Navas), Mark Eibes, Mark van Rensburg, Martijn Blankestijn, Martin Studer, Matthew Edwards, Matthew Pflueger, mauropalsgraaf, mbarak, Mehitabel, Michael Pigg, Mikael Moghadam, Mike Gehard (@mikegehard), MonadicBind, arjun.mukherjee@gmail.com, Stephen Arbogast, Narayan Iyer, @natewave, Netanel Rabinowitz, Nick Peterson, Nicolas Sitbon, Oier Blasco Linares, Oliver Daff, Oliver Schrenk, Olly Shaw, P Villela, pandaforme, Patrick Garrity, Paweł Włodarski from JUG Lodz, @peel, Peter Perhac, Phil Glover,

Chapter 1

Introduction

This is a book on strategies to create code in a functional programming (FP) style, seen through a Scala lens. If you understand most of the mechanics of Scala, but feel there is something missing in your understanding of how to use the language effectively, this book might be for you. If you don't know so much Scala, but are prepared to learn it as part of learning about functional programming, this book might also work. It covers the usual functional programming abstractions like monads and monoids, but more than that it tries to teach you how to think and program like a functional programmer. It's a book as much about process as it is about the code that results from process, and in particular it focuses on what I can metacognitive programming strategies.

I would guess most programmers would struggle to describe the process they use to write code. I expect some might mention “test driven development” and perhaps “pair programming”, but I wouldn’t expect much more from the general programming population. Both the above techniques come from eXtreme Programming, which dates to the late 90s, and you would hope our field had added new knowledge in that time. But it’s not really the fault of the developers—most of them haven’t been taught any explicit process. Our industry certainly likes to talk about process, in the form of agile, kanban boards, and so on, and in recent times a tremendous effort has spent on expanding those who are taught programming. However the actual

programming—the bit that produces the code that is the whole point of the endeavour—is still largely treated as magic. It doesn’t have to be that way.

Functional programmers love fancy words for simple ideas, so it’s no surprise I’m drawn to metacognitive programming strategies. Let’s unpack that phrase to see what it means. Metacognition means thinking about thinking. A lot of research has shown the benefits of metacognition in learning, and that it is an important part of developing expertise. Metacognition is not just one thing—it’s not sufficient to just tell someone to think about their thinking. Rather we should expect metacognition to be a collection of different strategies, some of which are general and some of which are domain specific. From this we get the idea of metacognitive programming strategies—explicitly naming and describing different thinking strategies that proficient programmers use.

I believe metacognitive programming strategies are useful for both beginners and experts. For beginners we can make programming a more systematic and repeatable process. Producing code no longer requires magic in the majority of cases, but rather the application of some well defined steps. For experts, the benefit is exactly the same. At least that is my experience (and I believe I’ve been programming long enough to call myself an expert.) By having an explicit process I can run it exactly the same way every day, which makes my code simpler to write and read, and saves my brain cycles for more important problems. In some ways this is an attempt to bring to programming the benefit that process and standardization has brought to manufacturing, particularly the “Toyota Way”. In Toyota’s process individuals are expected to think about how their work is done and how it can be improved. This is, in effect, metacognition for assembly lines. This is only possible if the actual work itself does not require their full attention. The dramatic improvements in productivity and quality in car manufacturing that Toyota pioneered speak to the effectiveness of this approach. Software development is more varied than car manufacturing but we should still expect some benefit, particularly given the primitive state of our current industry.

The question then becomes: what metacognitive strategies can programmers use? I believe that functional programming is particularly well suited to answer this question. A major theme in functional programming research is finding and naming useful code structures. Once we have discovered a useful abstraction we can get the programmer to ask themselves “would this

abstraction solve this problem?” This is essentially what the design patterns community did, also back in the nineties, but there is an important difference. The academic FP community strongly values formal models, which means that the building blocks of FP have a precision that design patterns lack. However there is more to process than categorizing the output. There is also the actual process of how the code comes to be. Code doesn’t usually spring fully formed from our keyboard, and in the iterative refinement of code we also find structure. Here the academic FP community has less to say, but there is a strong folklore of techniques such as “type driven development”

Over the last ten or so years of programming and teaching programming I’ve collected a wide range of strategies. Some come from others (for example, [How to Design Programs](#) and its many offshoots remain very influential for me) and some I’ve found myself. Ultimately I don’t think anything here is new; rather my contribution is in collecting and presenting these strategies as one coherent whole.

1.1 Three Levels for Thinking About Code

Let’s start thinking about thinking about programming with a model that describes three different levels that we can use to describe about code. The levels, from highest to lowest, are paradigm, theory, and craft. Each level provides guidance for the ones below.

The paradigm level refers to the programming paradigm, such as object-oriented or functional programming. You’re probably familiar with these terms, but what exactly is a programming paradigm? To me, the core of a programming paradigm is a set of principles that define, usually somewhat loosely, the properties of good code. A paradigm is also, implicitly, a claim that code that follows these principles will be better than code that does not. For functional programming I believe these principles are composition and reasoning. I’ll explain these shortly. Object-oriented programmers might point to, say, the SOLID principles as guiding their coding decisions.

The importance of the paradigm is that it provides criteria for choosing between different implementation strategies. There are many possible

solutions for any programming problem, and we can use the principles in the paradigm to decide which approach to take. For example, if we're a functional programmer we can consider how easily we can reason about a particular implementation, or how composable it is. Without the paradigm we have no basis for making a choice.

The theory level translates the broad principles of the paradigm to specific well defined techniques that apply to many languages within the paradigm. We are still, however, at a level above the code. Design patterns are an example in the object-oriented world. Algebraic data types are an example in functional programming. Most languages that are in the functional programming paradigm, such as Haskell and O'Caml, support algebraic data types, as do many languages that straddle multiple paradigms, such as Rust, Scala, and Swift.

The theory level is where we find most of our programming strategies.

At the craft level we get to actual code, and the language specific nuance that goes into it. An example in Scala is the implementation of algebraic data types in terms of `sealed trait` and `final case class` in Scala 2, or `enum` in Scala 3. There are many concerns at this level that are important for writing idiomatic code, such as placing constructors on companion objects in Scala, that are not relevant at the higher levels.

In the next section I'll describe the functional programming paradigm. The remainder of this book is primarily concerned with theory and craft. The theory is language agnostic but the craft is firmly in the world of Scala. Before we move onto the functional programming paradigm are two points I want to emphasize:

1. Paradigms are social constructs. They change over time. Object-oriented programming as practiced todays differs from from the style originally used in Simula and Smalltalk, and functional programming todays is very different from the original LISP code.
2. The three level organization is just a tool for thought. In real world is more complicated.

1.2 Functional Programming

This is a book about the techniques and practices of functional programming (FP). This naturally leads to the question: what is FP and what does it mean to write code in a functional style? It's common to view functional programming as a collection of language features, such as first class functions, or to define it as a programming style using immutable data and pure functions. (Pure functions always return the same output given the same input.) This was my view when I started down the FP route, but I now believe the true goals of FP are enabling local reasoning and composition. Language features and programming style are in service of these goals. Let me attempt to explain the meaning and value of local reasoning and composition.

1.2.1 What Functional Programming Is

I believe that functional programming is a hypothesis about software quality: that it is easier to write and maintain software that can be understood before it is run, and is built of small reusable components. The first property is known as local reasoning, and the second as composition. Let's address each in turn.

Local reasoning means we can understand pieces of code in isolation. When we see the expression `1 + 1` we know what it means regardless of the weather, the database, or the current status of our Kubernetes cluster. None of these external events can change it. This is a trivial and slightly silly example, but it illustrates the point. A goal of functional programming is to extend this ability across our code base.

It can help to understand local reasoning by looking at what it is not. Shared mutable state is out because relying on shared state means that other code can change what our code does without our knowledge. It means no global mutable configuration, as found in many web frameworks and graphics libraries for example, as any random code can change that configuration. Metaprogramming has to be carefully controlled. No [monkey patching](#), for example, as again it allows other code to change our code in non-obvious ways. As we can see, adapting code to enable local reasoning can mean quite some sweeping changes. However if we work in a language that embraces

functional programming this style of programming is the default.

Composition means building big things out of smaller things. Numbers are compositional. We can take any number and add one, giving us a new number. Lego is also compositional. We compose Lego by sticking it together. In the particular sense we're using composition we also require the original elements we combine don't change in any way when they are composed. When we create 2×2 by adding $1 + 1$ we get a new result that doesn't change what 1 means.

We can find compositional ways to model common programming tasks once we start looking for them. React components are one example familiar to many front-end developers: a component can consist of many components. HTTP routes can be modelled in a compositional way. A route is a function from an HTTP request to either a handler function or a value indicating the route did not match. We can combine routes as a logical or: try this route or, if it doesn't match, try this other route. Processing pipelines are another example that often use sequential composition: perform this pipeline stage and then this other pipeline stage.

1.2.1.1 Types

Types are not strictly part of functional programming but statically typed FP is the most popular form of FP and sufficiently important to warrant a mention. Types help compilers generate efficient code but types in FP are as much for the programmer as they are the compiler. Types express properties of programs, and the type checker automatically ensures that these properties hold. They can tell us, for example, what a function accepts and what it returns, or that a value is optional. We can also use types to express our beliefs about a program and the type checker will tell us if those beliefs are correct. For example, we can use types to tell the compiler we do not expect an error at a particular point in our code and the type checker will let us know if this is the case. In this way types are another tool for reasoning about code.

Type systems push programs towards particular designs, as to work effectively with the type checker requires designing code in a way the type checker can

understand. As modern type systems come to more languages they naturally tend to shift programmers in those languages towards a FP style of coding.

1.2.2 What Functional Programming Isn't

In my view functional programming is not about immutability, or keeping to “the substitution model of evaluation”, and so on. These are tools in service of the goals of enabling local reasoning and composition, but they are not the goals themselves. Code that is immutable always allows local reasoning, for example, but it is not necessary to avoid mutation to still have local reasoning. Here is an example of summing a collection of numbers.

```
def sum(numbers: List[Int]): Int = {
    var total = 0
    numbers.foreach(x => total = total + x)
    total
}
```

In the implementation we mutate `total`. This is ok though! We cannot tell from the outside that this is done, and therefore all users of `sum` can still use local reasoning. Inside `sum` we have to be careful when we reason about `total` but this block of code is small enough that it shouldn't cause any problems.

In this case we can reason about our code despite the mutation, but the Scala compiler can determine that this is ok. Scala allows mutation but it's up to us to use it appropriately. A more expressive type system, perhaps with features like Rust's, would be able to tell that `sum` doesn't allow mutation to be observed by other parts of the system¹. Another approach, which is the

¹The example I gave is fairly simple. A compiler that used [escape analysis](#) could recognize that no reference to `total` is possible outside `sum` and hence `sum` is pure (or referentially transparent). Escape analysis is a well studied technique. In the general case the problem is a lot harder. We'd often like to know that a value is only referenced once at various points in our program, and hence we can mutate that value without changes being observable in other parts of the program. This might be used, for example, to pass an accumulator through various processing stages. To do this requires a programming language with what is called a [substructural type system](#). Rust has such a system, with affine types. Linear types are in development for Haskell.

one taken by Haskell, is to disallow all mutation and thus guarantee it cannot cause problems.

Mutation also interferes with composition. For example, if a value relies on internal state then composing it may produce unexpected results. Consider Scala's `Iterator`. It maintains internal state that is used to generate the next value. If we have two `Iterators` we might want to combine them into one `Iterator` that yields values from the two inputs. The `zip` method does this.

This works if we pass two distinct generators to `zip`.

```
val it = Iterator(1, 2, 3, 4)

val it2 = Iterator(1, 2, 3, 4)

it.zip(it2).next()
// res0: Tuple2[Int, Int] = (1, 1)
```

However if we pass the same generator twice we get a surprising result.

```
val it3 = Iterator(1, 2, 3, 4)

it3.zip(it3).next()
// res1: Tuple2[Int, Int] = (1, 2)
```

The usual functional programming solution is to avoid mutable state but we can envisage other possibilities. For example, an [effect tracking system](#) would allow us to avoid combining two generators that use the same memory region. These systems are still research projects, however.

So in my opinion immutability (and purity, referential transparency, and no doubt more fancy words that I have forgotten) have become associated with functional programming because they guarantee local reasoning and composition, and until recently we didn't have the language tools to automatically distinguish safe uses of mutation from those that cause problems. Restricting ourselves to immutability is the easiest way to ensure the desirable properties of functional programming, but as languages evolve this might come to be regarded as a historical artifact.

1.2.3 Why It Matters

I have described local reasoning and composition but have not discussed their benefits. Why are they desirable? The answer is that they make efficient use of knowledge. Let me expand on this.

We care about local reasoning because it allows our ability to understand code to scale with the size of the code base. We can understand module A and module B in isolation, and our understanding does not change when we bring them together in the same program. By definition if both A and B allow local reasoning there is no way that B (or any other code) can change our understanding of A, and vice versa. If we don't have local reasoning every new line of code can force us to revisit the rest of the code base to understand what has changed. This means it becomes exponentially harder to understand code as it grows in size as the number of interactions (and hence possible behaviours) grows exponentially. We can say that local reasoning is compositional. Our understanding of module A calling module B is just our understanding of A, our understanding of B, and whatever calls A makes to B.

We introduced numbers and Lego as examples of composition. They have an interesting property in common: the operations that we can use to combine them (for example, addition, subtraction, and so on for numbers; for Lego the operation is "sticking bricks together") give us back the same kind of thing. A number multiplied by a number is a number. Two bits of Lego stuck together is still Lego. This property is called closure: when you combine things you end up with the same kind of thing. Closure means you can apply the combining operations (sometimes called combinators) an arbitrary number of times. No matter how many times you add one to a number you still have a number and can still add or subtract or multiply or...you get the idea. If we understand module A, and the combinators that A provides are closed, we can build very complex structures using A without having to learn new concepts! This is also one reason functional programmers tend to like abstractions such as monads (beyond liking fancy words): they allow us to use one mental model in lots of different contexts.

In a sense local reasoning and composition are two sides of the same coin. Local reasoning is compositional; composition allows local reasoning. Both make code easier to understand.

1.2.4 The Evidence for Functional Programming

I've made arguments in favour of functional programming and I admit I am biased—I do believe it is a better way to develop code than imperative programming. However, is there any evidence to back up my claim? There has not been much research on the effectiveness of functional programming, but there has been a reasonable amount done on static typing. I feel static typing, particularly using modern type systems, serves as a good proxy for functional programming so let's look at the evidence there.

In the corners of the Internet I frequent the common refrain is that [static typing has negligible effect on productivity](#). I decided to look into this and was surprised that the majority of the results I found support the claim that static typing increases productivity. For example, the literature review in [this dissertation](#) (section 2.3, p16–19) shows a majority of results in favour of static typing, in particular the most recent studies. However the majority of these studies are very small and use relatively inexperienced developers—which is noted in the review by Dan Luu that I linked. My belief is that functional programming comes into its own on larger systems. Furthermore, programming languages, like all tools, require proficiency to use effectively. I'm not convinced very junior developers have sufficient skill to demonstrate a significant difference between languages.

To me the most useful evidence of the effectiveness of functional programming is that industry is adopting functional programming en masse. Consider, say, the widespread and growing adoption of Typescript and React. If we are to argue that FP as embodied by Typescript or React has no value we are also arguing that the thousands of Javascript developers who have switched to using them are deluded. At some point this argument becomes untenable.

This doesn't mean we'll all be using Haskell in five years. More likely we'll see something like the shift to object-oriented programming of the nineties: Smalltalk was the paradigmatic example of OO, but it was more familiar languages like C++ and Java that brought OO to the mainstream. In the case of FP this probably means languages like Scala, Swift, Kotlin, or Rust, and mainstream languages like Javascript and Java continuing to adopt more FP features.

1.2.5 Final Words

I've given my opinion on functional programming—that the real goals are local reasoning and composition, and programming practices like immutability are in service of these. Other people may disagree with this definition, and that's ok. Words are defined by the community that uses them, and meanings change over time.

Functional programming emphasises formal reasoning, and there are some implications that I want to briefly touch on.

Firstly, I find that FP is most valuable in the large. For a small system it is possible to keep all the details in our head. It's when a program becomes too large for anyone to understand all of it that local reasoning really shows its value. This is not to say that FP should not be used for small projects, but rather that if you are, say, switching from an imperative style of programming you shouldn't expect to see the benefit when working on toy projects.

The formal models that underlie functional programming allow systematic construction of code. This is in some ways the reverse of reasoning: instead of taking code and deriving properties and start from some properties and derive code. This sounds very academic but is in fact very practical and how I, for example, develop most of my code.

Finally, reasoning is not the only way to understand code. It's valuable to appreciate the limitations of reasoning, other methods for gaining understanding, and using a variety of strategies depending on the situation.

Part I

Theory

Chapter 2

Algebraic Data Types

This chapter has our first example of a programming strategy: **algebraic data types**. Any data we can describe using logical ands and logical ors is an algebraic data type. Once we recognize an algebraic data type we get three things for free:

- the Scala representation of the data;
- a **structural recursion** skeleton to transform the algebraic data type into any other type; and
- a **structural corecursion** skeleton to construct the algebraic data type from any other type.

The key point is this: from an implementation independent representation of data we can automatically derive most of the interesting implementation specific parts of working with that data.

We'll start with some examples of data, from which we'll extract the common structure that motivates algebraic data types. We will then look at their representation in Scala 2 and Scala 3. Next we'll turn to structural recursion for transforming algebraic data types, followed by structural corecursion for constructing them. We'll finish by looking at the algebra of algebraic data types, which is interesting but not essential.

2.1 Building Algebraic Data Types

Let's start with some examples of data from a few different domains. These are simplified descriptions but they are all representative of real applications.

A user in a discussion forum will typically have a screen name, an email address, and a password. Users also typically have a specific role: normal user, moderator, or administrator, for example. From this we get the following data:

- a user is a screen name, an email address, a password, and a role; and
- a role is normal, moderator, or administrator.

A product in an e-commerce store might have a stock keeping unit (a unique identifier for each variant of a product), a name, a description, a price, and a discount.

In two-dimensional vector graphics it's typical to represent shapes as a path, which is a sequence of actions of a virtual pen. The possible actions are usually straight lines, Bezier curves, or movement that doesn't result in visible output. A straight line has an end point (the starting point is implicit), a Bezier curve has two control points and an end point, and a move has an end point.

What is common between all the examples above is that the individual elements—the atoms, if you like—are connected by either a logical and or a logical or. For example, a user is a screen name **and** an email address **and** a password **and** a role. A 2D action is a straight line **or** a Bezier curve **or** a move. This is the core of algebraic data types: an algebraic data type is data that is combined using logical ands or logical ors. Conversely, whenever we can describe data in terms of logical ands and logical ors we have an algebraic data type.

2.1.1 Sums and Products

Being functional programmers, we can't let a simple concept go without attaching some fancy jargon:

- a **product type** means a logical and; and

- a sum type means a logical or.

So algebraic data types consist of sum and product types.

2.1.2 Closed Worlds

Algebraic data types are closed worlds, which means they cannot be extended after they have been defined. In practical terms this means we have to modify the source code where we define the algebraic data type if we want to add or remove elements.

The closed world property is important because it gives us guarantees we would not otherwise have. In particular, it allows the compiler to check, when we use an algebraic data type, that we handle all possible cases and alert us if we don't. This is known as **exhaustivity checking**. This is an example of how functional programming prioritizes reasoning about code—in this case automated reasoning by the compiler—over other properties such as extensibility.

2.2 Algebraic Data Types in Scala

Now we know what algebraic data types are, we can turn to their representation in Scala. The important point here is that the translation to Scala is entirely determined by the structure of the data; no thinking is required! This means the work is in finding the structure of the data that best represents the problem at hand. Work out the structure of the data and the code directly follows from it.

As algebraic data types are defined in terms of logical ands and logical ors, to represent algebraic data types in Scala we must know how to represent these two concepts in Scala. Scala 3 simplifies the representation of algebraic data types compared to Scala 2, so we'll look at each language version separately.

I'm assuming that you're familiar with the language features we use to represent algebraic data types in Scala, but not with their correspondence to algebraic data types.

2.2.1 Algebraic Data Types in Scala 3

In Scala 3 a logical and (a product type) is represented by a `final case class`. If we define a product type A is B **and** C, the representation in Scala 3 is

```
final case class A(b: B, c: C)
```

Not everyone makes their case classes `final`, but they should. A non-final case class can still be extended by a class, which breaks the closed world criteria for algebraic data types.

A logical or (a sum type) is represented by an `enum`. For the sum type A is a B **or** C the Scala 3 representation is

```
enum A {
  case B
  case C
}
```

There are a few wrinkles to be aware of.

If we have a sum of products, such as:

- A is a B or C; and
- B is a D and E; and
- C is a F and G

the representation is

```
enum A {
  case B(d: D, e: E)
  case C(f: F, g: G)
}
```

In other words we don't write `final case class` inside an `enum`. You also can't nest `enum` inside `enum`. Nested logical ors can be rewritten into a single logical or containing only logical ands (known as disjunctive normal form) so this is not a limitation in practice. However the Scala 2 representation is still available in Scala 3 should you want more expressivity.

2.2.2 Algebraic Data Types in Scala 2

A logical and (product type) has the same representation in Scala 2 as in Scala 3. If we define a product type A is B **and** C, the representation in Scala 2 is

```
final case class A(b: B, c: C)
```

A logical or (a sum type) is represented by a sealed abstract class. For the sum type A is a B **or** C the Scala 2 representation is

```
sealed abstract class A
final case class B() extends A
final case class C() extends A
```

Scala 2 has several little tricks to defining algebraic data types.

Firstly, instead of using a sealed abstract class you can use a sealed trait . There isn't much practical difference between the two. When teaching beginners I'll often use sealed trait to avoid having to introduce abstract class. I believe sealed abstract class has slightly better performance and Java interoperability but I haven't tested this. I also think sealed abstract class is closer, semantically, to the meaning of a sum type.

For extra style points we can extend Product with Serializable from sealed abstract class. Compare the reported types below with and without this little addition.

Let's first see the code without extending Product and Serializable.

```
sealed abstract class A
final case class B() extends A
final case class C() extends A

val list = List(B(), C())
// list: List[A extends Product with Serializable] = List(B(), C())
```

Notice how the type of list includes Product and Serializable.

Now we have extending Product and Serializable.

```
sealed abstract class A extends Product with Serializable
final case class B() extends A
final case class C() extends A

val list = List(B(), C())
// list: List[A] = List(B(), C())
```

Much easier to read!

You'll only see this in Scala 2. Scala 3 has the concept of **transparent traits**, which aren't reported in inferred types, so you'll see the same output in Scala 3 no matter whether you add `Product` and `Serializable` or not.

Finally, if a logical and holds no data we can use a `case object` instead of a `case class`. For example, if we're defining some type `A` that holds no data we can just write

```
case object A
```

There is no need to mark the `case object` as `final`, as objects cannot be extended.

2.2.3 Examples

Let's make the discussion above more concrete with some examples.

2.2.3.1 Role and User

In the discussion forum example, we said a role is normal, moderator, or administrator. This is a logical or, so we can directly translate it to Scala using the appropriate pattern. In Scala 3 we write

```
enum Role {
  case Normal
  case Moderator
```

```
case Administrator  
}
```

In Scala 2 we write

```
sealed abstract class Role extends Product with Serializable  
case object Normal extends Role  
case object Moderator extends Role  
case object Administrator extends Role
```

The cases within a role don't hold any data, so we used a case object in the Scala 2 code.

We defined a user as a screen name, an email address, a password, and a role. In both Scala 3 and Scala 2 this becomes

```
final case class User(screenName: String, emailAddress: String,  
                      password: String, role: Role)
```

I've used `String` to represent most of the data within a `User`, but in real code we might want to define separate types for each field.

2.2.3.2 Paths

We defined a path as a sequence of actions of a virtual pen. The possible actions are usually straight lines, Bezier curves, or movement that doesn't result in visible output. A straight line has an end point (the starting point is implicit), a Bezier curve has two control points and an end point, and a move has an end point.

This has a straightforward translation to Scala. We can represent paths as the following in both Scala 3 and Scala 2.

```
final case class Path(actions: Seq[Action])
```

An action is a logical or, so we have different representations in Scala 3 and Scala 2. In Scala 3 we'd write

```
enum Action {
  case Line(end: Point)
  case Curve(cp1: Point, cp2: Point, end: Point)
  case Move(end: Point)
}
```

where `Point` is a suitable representation of a two-dimensional point.

In Scala 2 we have to go with the more verbose

```
sealed abstract class Action extends Product with Serializable
final case class Line(end: Point) extends Action
final case class Curve(cp1: Point, cp2: Point, end: Point) extends
    Action
final case class Move(end: Point) extends Action
```

2.2.4 Representing ADTs in Scala 3

We've seen that the Scala 3 representation of algebraic data types, using `enum`, is more compact than the Scala 2 representation. However the Scala 2 representation is still available. Should you ever use the Scala 2 representation in Scala 3? There are a few cases where you may want to:

- Scala 3's doesn't currently support nested `enums` (`enums` within `enums`). This may change in the future, but right now it can be more convenient to use the Scala 2 representation to express this without having to convert to disjunctive normal form.
- Scala 2's representation can express things that are almost, but not quite, algebraic data types. For example, if you define a method on an `enum` you must be able to define it for all the members of the `enum`. Sometimes you want a case of an `enum` to have methods that are only defined for that case. To implement this you'll need to use the Scala 2 representation instead.

2.3 Structural Recursion

Structural recursion is our second programming strategy. Algebraic data types tell us how to create data given a certain structure. Structural recursion tells us how to transform an algebraic data type into any other type. Given an algebraic data type, the transformation can be implemented using structural recursion.

As with algebraic data types, there is distinction between the concept of structural recursion and the implementation in Scala. This is more obvious because there are two ways to implement structural recursion in Scala: via pattern matching or via dynamic dispatch. We'll look at each in turn.

2.3.1 Pattern Matching

I'm assuming you're familiar with pattern matching in Scala, so I'll only talk about how to implement structural recursion using pattern matching. Remember there are two kinds of algebraic data types: sum types (logical ors) and product types (logical ands). We have corresponding rules for structural recursion implemented using pattern matching:

1. For each branch in a sum type we have a distinct case in the pattern match; and
2. Each case corresponds to a product type with the pattern written in the usual way.

Let's see this in code, using an example ADT that includes both sum and product types:

- A is a B or C; and
- B is a D and E; and
- C is a F and G

which we represent (in Scala 3) as

```
enum A {
  case B(d: D, e: E)
  case C(f: F, g: G)
}
```

Following the rules above means a structural recursion would look like

```
anA match {
  case B(d, e) => ???
  case C(f, g) => ???
}
```

The ??? bits are problem specific, and we cannot give a general solution for them. However we'll soon see strategies to help create them.

2.3.2 The Recursion in Structural Recursion

At this point you might be wondering where the recursion in structural recursion comes from. This is an additional rule for recursion: whenever the data is recursive the method is recursive in the same place.

Let's see this in action for a real data type.

We can define a list with elements of type A as:

- the empty list; or
- a pair containing an A and a tail, which is a list of A.

This is exactly the definition of `List` in the standard library. Notice it's an algebraic data type as it consists of sums and products. It is also recursive: in the pair case the tail is itself a list.

We can directly translate this to code, using the strategy for algebraic data types we saw previously. In Scala 3 we write

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])
}
```

Let's implement `map` for `MyList`. We start with the method skeleton specifying just the name and types.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    ???
}
```

Our first step is to recognize that `map` can be written using a structural recursion. `MyList` is an algebraic data type, `map` is transforming this algebraic data type, and therefore structural recursion is applicable. We now apply the structural recursion strategy, giving us

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    this match {
      case Empty() => ???
      case Pair(head, tail) => ???
    }
}
```

I forgot the recursion rule! The data is recursive in the `tail` of `Pair`, so `map` is recursive there as well.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])
```

```
def map[B](f: A => B): MyList[B] =
  this match {
    case Empty() => ???
    case Pair(head, tail) => ??? tail.map(f)
  }
}
```

I left the `???` to indicate that we haven't finished with that case.

Now we can move on to the problem specific parts. Here we have three strategies to help us:

1. reasoning independently by case;
2. assuming recursion is correct; and
3. following the types

The first two are specific to structural recursion, while the final one is a general strategy we can use in many situations. Let's briefly discuss each and then see how they apply to our example.

The first strategy is relatively simple: when we consider the problem specific code on the right hand side of a pattern matching case, we can ignore the code in any other pattern match cases. So, for example, when considering the case for `Empty` above we don't need to worry about the case for `Pair`, and vice versa.

The next strategy is a little bit more complicated, and has to do with recursion. Remember that the structural recursion strategy tells us where to place any recursive calls. This means we don't have to think through the recursion. Instead we assume the recursive call will correctly compute what it claims, and only consider how to further process the result of the recursion. The result is guaranteed to be correct so long as we get the non-recursive parts correct.

In the example above we have the recursion `tail.map(f)`. We can assume this correctly computes `map` on the tail of the list, and we only need to think about what we should do with the remaining data: the head and the result of the recursive call.

It's this property that allows us to consider cases independently. Recursive calls are the only thing that connect the different cases, and they are given to us by the structural recursion strategy.

Our final strategy is **following the types**. It can be used in many situations, not just structural recursion, so I consider it a separate strategy. The core idea is to use the information in the types to restrict the possible implementations. We can look at the types of inputs and outputs to help us.

Now let's use these strategies to finish the implementation of `map`. We start with

```
enum MyList[A] {  
    case Empty()  
    case Pair(head: A, tail: MyList[A])  
  
    def map[B](f: A => B): MyList[B] =  
        this match {  
            case Empty() => ???  
            case Pair(head, tail) => ??? tail.map(f)  
        }  
}
```

Our first strategy is to consider the cases independently. Let's start with the `Empty` case. There is no recursive call here, so reasoning using structural recursion doesn't come into play. Let's instead use the types. There is no input here other than the `Empty` case we have already matched, so we cannot use the input types to further restrict the code. However we can use the output types. We're trying to create a `MyList[B]`. There are only two ways to create a `MyList[B]`: an `Empty` or a `Pair`. To create a `Pair` we need a head of type `B`, which we don't have. So we can only use `Empty`. *This is the only possible code we can write.* The types are sufficiently restrictive that we cannot write incorrect code for this case.

```
enum MyList[A] {  
    case Empty()  
    case Pair(head: A, tail: MyList[A])  
  
    def map[B](f: A => B): MyList[B] =  
        this match {  
            case Empty() => Empty()  
            case Pair(head, tail) => ??? tail.map(f)  
        }  
}
```

```
}
```

Now let's move to the `Pair` case. We can apply both the structural recursion reasoning strategy and following the types. Let's use each in turn.

The case for `Pair` is

```
case Pair(head, tail) => ??? tail.map(f)
```

Remember we can consider this independently of the other case. We assume the recursion is correct. This means we only need to think about what we should do with the head, and how we should combine this result with `tail.map(f)`. Let's now follow the types to finish the code. Our goal is to produce a `MyList[B]`. We already have the following available:

- `tail.map(f)`, which has type `MyList[B]`;
- `head`, with type `A`;
- `f`, with type `A => B`; and
- the constructors `Empty` and `Pair`.

We could return just `Empty`, matching the case we've already written. This has the correct type but we might expect it is not the correct answer because it does not use the result of the recursion, `head`, or `f` in any way.

We could return just `tail.map(f)`. This has the correct type but we might expect it is not correct because we don't use `head` or `f` in any way.

We can call `f` on `head`, producing a value of type `B`, and then combine this value and the result of the recursive call using `Pair` to produce a `MyList[B]`. This is the correct solution.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    this match {
      case Empty() => Empty()
      case Pair(head, tail) => Pair(f(head), tail.map(f))
```

```
    }  
}
```

If you've followed this example you've hopefully seen how we can use the three strategies to systematically find the correct implementation. Notice how we interleaved the recursion strategy and following the types to guide us to a solution for the `Pair` case. Also note how following the types alone gave us three possible implementations for the `Pair` case. In this code, and as is usually the case, the solution was the implementation that used all of the available inputs.

2.3.3 Exhaustivity Checking

Remember that algebraic data types are a closed world: they cannot be extended once defined. The Scala compiler can use this to check that we handle all possible cases in a pattern match, so long as we write the pattern match in a way the compiler can work with. This is known as exhaustivity checking.

Here's a simple example. We start by defining a straight-forward algebraic data type.

```
// Some of the possible units for lengths in CSS  
enum CssLength {  
    case Em(value: Double)  
    case Rem(value: Double)  
    case Pt(value: Double)  
}
```

If we write a pattern match using the structural recursion strategy, the compiler will complain if we're missing a case.

```
import CssLength.*  
  
CssLength.Em(2.0) match {  
    case Em(value) => value  
    case Rem(value) => value
```

```
}

// -- [E029] Pattern Match Exhaustivity Warning:
-----  

// 1 |CssLength.Em(2.0) match {  

//   |~~~~~  

//   |match may not be exhaustive.  

//   |  

//   |It would fail on pattern case: CssLength.Pt(_)  

//   |  

//   |longer explanation available when compiling with `~-explain`
```

Exhaustivity checking is incredibly useful. For example, if we add or remove a case from an algebraic data type, the compiler will tell us all the pattern matches that need to be updated.

2.3.4 Dynamic Dispatch

Using dynamic dispatch to implement structural recursion is an implementation technique that may feel more natural to people with a background in object-oriented programming.

The dynamic dispatch approach consists of:

1. defining an *abstract method* at the root of the algebraic data types; and
 2. implementing that abstract method at every leaf of the algebraic data type.

This implementation technique is only available if we use the Scala 2 encoding of algebraic data types.

Let's see it in the `MyList` example we just looked at. Our first step is to rewrite the definition of `MyList` to the Scala 2 style.

```
sealed abstract class MyList[A] extends Product with Serializable
final case class Empty[A]() extends MyList[A]
final case class Pair[A](head: A, tail: MyList[A]) extends MyList[A]
```

Next we define an abstract method for `map` on `MyList`.

```
sealed abstract class MyList[A] extends Product with Serializable {
  def map[B](f: A => B): MyList[B]
}
final case class Empty[A]() extends MyList[A]
final case class Pair[A](head: A, tail: MyList[A]) extends MyList[A]
```

Then we implement `map` on the concrete subtypes `Empty` and `Pair`.

```
sealed abstract class MyList[A] extends Product with Serializable {
  def map[B](f: A => B): MyList[B]
}
final case class Empty[A]() extends MyList[A] {
  def map[B](f: A => B): MyList[B] =
    Empty()
}
final case class Pair[A](head: A, tail: MyList[A]) extends MyList[A] {
  def map[B](f: A => B): MyList[B] =
    Pair(f(head), tail.map(f))
}
```

We can use exactly the same strategies we used in the pattern matching case to create this code. The implementation technique is different but the underlying concept is the same.

Given we have two implementation strategies, which should we use? If we're using `enum` in Scala 3 we don't have a choice; we must use pattern matching. In other situations we can choose between the two. I prefer to use pattern matching when I can, as it puts the entire method definition in one place. However, Scala 2 in particular has problems inferring types in some pattern matches. In these situations we can use dynamic dispatch instead. We'll learn more about this when we look at generalized algebraic data types.

2.3.5 Folds as Structural Recursions

Let's finish by looking at the `fold` method as an abstraction over structural recursion. We know that every algebraic data type has a structural recursion skeleton that is determined entirely by the structure of the algebraic data type. For `MyList`, defined as

```
enum MyList[A] {
    case Empty()
    case Pair(head: A, tail: MyList[A])
}
```

the skeleton is

```
aList match {
    case Empty() => ???
    case Pair(head, tail) => ??? recursion(tail)
}
```

For any algebraic data type we can define at least one method, called a fold, that captures all the parts of structural recursion that don't change and allows the caller to specify all the problem specific parts. For `MyList` this means defining a method

```
def fold[A, B](list: MyList[A]): B =
list match {
    case Empty() => ???
    case Pair(head, tail) => ??? fold(tail)
}
```

where `B` is the type the caller wants to create.

To complete `fold` we add method parameters for the problem specific (???) parts. In the case for `Empty`, we need a value of type `B` (notice that I'm following the types here).

```
def fold[A,B](list: MyList[A], empty: B): B =
list match {
    case Empty() => empty
    case Pair(head, tail) => ??? fold(tail, empty)
}
```

For the `Pair` case, we have the head of type `A` and the recursion producing a value of type `B`. This means we need a function to combine these two values.

```
def foldRight[A,B](list: MyList[A], empty: B, f: (A, B) => B): B =
  list match {
    case Empty() => empty
    case Pair(head, tail) => f(head, foldRight(tail, empty, f))
  }
```

This is `foldRight` (and I've renamed the method to indicate this). You might have noticed there is another valid solution. Both `empty` and the recursion produce values of type `B`. If we follow the types we can come up with

```
def foldLeft[A,B](list: MyList[A], empty: B, f: (A, B) => B): B =
  list match {
    case Empty() => empty
    case Pair(head, tail) => foldLeft(tail, f(head, empty), f)
  }
```

which is `foldLeft`, the tail-recursive variant of `fold` for a list.

We can follow the same process for any algebraic data type to create its folds. The rules are:

- a fold is a function from the algebraic data type and additional parameters to some generic type that I'll call `B` below for simplicity;
- the fold has one additional parameter for each case in a logical or;
- each parameter is a function, with result of type `B` and parameters that have the same type as the corresponding constructor arguments *except* recursive values are replaced with `B`; and
- if the constructor has no arguments (for example, `Empty`) we can use a value of type `B` instead of a function with no arguments.

Returning to `MyList`, it has:

- two cases, and hence two parameters to fold (other than the parameter that is the list itself);
- `Empty` is a constructor with no arguments and hence we use a parameter of type `B`; and
- `Pair` is a constructor with one parameter of type `A` and one recursive parameter, and hence the corresponding function has type `(A, B) => B`.

2.4 Structural Corecursion

Structural corecursion is the opposite—more correctly, the dual—of structural recursion. Whereas structural recursion tells us how to take apart an algebraic data type, structural corecursion tells us how to build up an algebraic data type. We can use structural corecursion whenever the output of a method or function is an algebraic data type.

2.4.0.1 Duality in Functional Programming

Duality means that there is some concept or structure that can be translated in a one-to-one fashion to some other concept or structure. Duality is often indicated by attaching the co- prefix to a term. So corecursion is the dual of recursion, and sum types, also known as coproducts, are the dual of product types.

Duality is one of the main themes of this book. By relating concepts as duals we can transfer knowledge from one domain to another.

Structural recursion works by considering all the possible inputs (which we usually represent as patterns), and then working out what we do with each input case. Structural corecursion works by considering all the possible outputs, which are the constructors of the algebraic data type, and then working out the conditions under which we'd call each constructor.

Let's return to the list with elements of type A, defined as:

- the empty list; or
- a pair containing an A and a tail, which is a list of A.

In Scala 3 we write

```
enum MyList[A] {  
    case Empty()
```

```
    case Pair(head: A, tail: MyList[A])
}
```

We can use structural corecursion if we're writing a method that produces a `MyList`. A good example is `map`:

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    ???
}
```

The structural corecursion strategy says we write down all the constructors and then consider the conditions that will cause us to call each constructor. So our starting point is to just write down the two constructors, and put in dummy conditions.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    if ??? then Empty()
    else Pair(???, ???)
}
```

We can also apply the recursion rule: where the data is recursive so is the method.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    if ??? then Empty()
    else Pair(???, ???.map(f))
}
```

To complete the left-hand side we can use the strategies we've already seen:

- we can use structural recursion to tell us there are two possible conditions; and
- we can follow the types to align these conditions with the code we have already written.

In short order we arrive at the correct solution

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])

  def map[B](f: A => B): MyList[B] =
    this match {
      case Empty() => Empty()
      case Pair(head, tail) => Pair(f(head), tail.map(f))
    }
}
```

There are a few interesting points here. Firstly, we should acknowledge that `map` is both a structural recursion and a structural corecursion. This is not always the case. For example, `foldLeft` and `foldRight` are not structural corecursions because they are not constrained to only produce an algebraic data type. Secondly, note that when we walked through the process of creating `map` as a structural recursion we implicitly used the structural corecursion pattern, as part of following the types. We recognised that we were producing a `List`, that there were two possibilities for producing a `List`, and then worked out the correct conditions for each case. Formalizing structural corecursion as a separate strategy allows us to be more conscious of where we apply it. Finally, notice how I switched from an `if` expression to a pattern match expression as we progressed through defining `map`. This is perfectly fine. Both kinds of expression can achieve the same effect, though if we wanted to continue using an `if` we'd have to define a method (for example, `isEmpty`) that allows us to distinguish an `Empty` element from a `Pair`. This method would have to use pattern matching in its implementation, so avoiding pattern matching directly is just pushing it elsewhere.

2.4.1 Unfolds as Structural Corecursion

Just as we could abstract structural recursion as a fold, for any given algebraic data type we can abstract structural corecursion as an unfold. Unfolds are much less commonly used than folds, but they are still a nice tool to have.

Let's work through the process of deriving unfold, using `MyList` as our example again.

```
enum MyList[A] {
  case Empty()
  case Pair(head: A, tail: MyList[A])
}
```

The corecursion skeleton is

```
if ??? then MyList.Empty()
else MyList.Pair(???, recursion(???))
```

We start defining our method `unfold` so we can fill in the missing pieces. I'm using the recursion rule immediately in the code below, to save a bit of time in the derivation.

```
def unfold[A, B](seed: A): MyList[B] =
  if ??? then MyList.Empty()
  else MyList.Pair(???, unfold(seed))
```

We can abstract the condition using a function from `A => Boolean`.

```
def unfold[A, B](seed: A, stop: A => Boolean): MyList[B] =
  if stop(seed) then MyList.Empty()
  else MyList.Pair(???, unfold(seed, stop))
```

Now we need to handle the case for `Pair`. We have a value of type `A` (`seed`), so to create the head element of `Pair` we can ask for a function `A => B`

```
def unfold[A, B](seed: A, stop: A => Boolean, f: A => B): MyList[B] =
  if stop(seed) then MyList.Empty()
  else MyList.Pair(f(seed), unfold(???, stop, f))
```

Finally we need to update the current value of seed to the next value. That's a function $A \Rightarrow A$.

```
def unfold[A, B](seed: A, stop: A => Boolean, f: A => B, next: A => A)
  : MyList[B] =
  if stop(seed) then MyList.Empty()
  else MyList.Pair(f(seed), unfold(next(seed), stop, f, next))
```

At this point we're done. Let's see that `unfold` is useful by declaring some other methods in terms of it. We're going to declare `map`, which we've already seen is a structural corecursion, using `unfold`. We will also define `fill` and `iterate`, which are methods that construct lists and correspond to the methods with the same names on `List` in the Scala standard library.

To make this easier to work with I'm going to declare `unfold` as a method on the `MyList` companion object. I have made a slight tweak to the definition to make type inference work a bit better. In Scala, types inferred for one method parameter cannot be used for other method parameters in the same parameter list. However, types inferred for one method parameter list can be used in subsequent lists. Separating the function parameters from the `seed` parameter means that the value inferred for `A` from `seed` can be used for inference of the function parameters' input parameters.

I have also declared some **destructor** methods, which are methods that take apart an algebraic data type. For `MyList` these are `head`, `tail`, and the predicate `isEmpty`. We'll talk more about these a bit later.

Here's our starting point.

```
enum MyList[A] {
  case Empty()
  case Pair(_head: A, _tail: MyList[A])

  def isEmpty: Boolean =
    this match {
```

```

    case Empty() => true
    case _         => false
}

def head: A =
  this match {
    case Pair(head, _) => head
  }

def tail: MyList[A] =
  this match {
    case Pair(_, tail) => tail
  }
}

object MyList {
  def unfold[A, B](seed: A)(stop: A => Boolean, f: A => B, next: A =>
  A): MyList[B] =
    if stop(seed) then MyList.Empty()
    else MyList.Pair(f(seed), unfold(next(seed))(stop, f, next))
}

```

Now let's define the constructors `fill` and `iterate`, and `map`, in terms of `unfold`. I think the constructors are a bit simpler, so I'll do those first.

```

object MyList {
  def unfold[A, B](seed: A)(stop: A => Boolean, f: A => B, next: A =>
  A): MyList[B] =
    if stop(seed) then MyList.Empty()
    else MyList.Pair(f(seed), unfold(next(seed))(stop, f, next))

  def fill[A](n: Int)(elem: => A): MyList[A] =
    ???

  def iterate[A](start: A, len: Int)(f: A => A): MyList[A] =
    ???
}

```

Here I've just added the method skeletons, which are taken straight from the `List` documentation. To implement these methods we can use one of two strategies:

- reasoning about loops in the way we might in an imperative language;

or

- reasoning about structural recursion over the natural numbers.

Let's talk about each in turn.

You might have noticed that the parameters to `unfold` are almost exactly those you need to create a for-loop in a language like Java. A classic for-loop, of the `for(i = 0; i < n; i++)` kind, has four components:

1. the initial value of the loop counter;
2. the stopping condition of the loop;
3. the statement that advances the counter; and
4. the body of the loop that uses the counter.

These correspond to the `seed`, `stop`, `next`, and `f` parameters of `unfold` respectively.

Loop variants and invariants are the standard way of reasoning about imperative loops. I'm not going to describe them here, as you have probably already learned how to reason about loops (though perhaps not using these terms). Instead I'm going to discuss the second reasoning strategy, which relates writing `unfold` to something we've already discussed: structural recursion.

Our first step is to note that natural numbers (the integers 0 and larger) are conceptually algebraic data types even though the implementation in Scala—using `Int`—is not. A natural number is either:

- zero; or
- $1 + \text{a natural number}$.

It's the simplest possible algebraic data type that is both a sum and a product type.

Once we see this, we can use the reasoning tools for structural recursion for creating the parameters to `unfold`. Let's show how this works with `fill`. The `n` parameter tells us how many elements there are in the `List` we're creating. The

`elem` parameter creates those elements, and is called once for each element. So our starting point is to consider this as a structural recursion over the natural numbers. We can take `n` as seed, and `stop` as the function `x => x == 0`. These are the standard conditions for a structural recursion over the natural numbers. What about `next`? Well, the definition of natural numbers tells us we should subtract one in the recursive case, so `next` becomes `x => x - 1`. We only need `f`, and that comes from the definition of how `fill` is supposed to work. We create the value from `elem`, so `f` is just `_ => elem`

```
object MyList {
  def unfold[A, B](seed: A)(stop: A => Boolean, f: A => B, next: A =>
    A): MyList[B] =
    if stop(seed) then MyList.Empty()
    else MyList.Pair(f(seed), unfold(next(seed))(stop, f, next))

  def fill[A](n: Int)(elem: => A): MyList[A] =
    unfold(n)(_ == 0, _ => elem, _ - 1)

  def iterate[A](start: A, len: Int)(f: A => A): MyList[A] =
    ???
}
```

We should check that our implementation works as intended. We can do this by comparing it to `List.fill`.

```
List.fill(5)(1)
// res6: List[Int] = List(1, 1, 1, 1, 1)
MyList.fill(5)(1)
// res7: MyList[Int] = MyList(1, 1, 1, 1, 1)

var counter = 0
def getAndInc(): Int = {
  val temp = counter
  counter = counter + 1
  temp
}

List.fill(5)(getAndInc())
// res8: List[Int] = List(0, 1, 2, 3, 4)
counter = 0
```

```
MyList.fill(5)(getAndInc())
// res10: MyList[Int] = MyList(0, 1, 2, 3, 4)
```

Exercise: Iterate

Implement `iterate` using the same reasoning as we did for `fill`. This is slightly more complex than `fill` as we need to keep two bits of information: the value of the counter and the value of type A.

See the solution

Exercise: Map

Once you've completed `iterate`, try to implement `map` in terms of `unfold`. You'll need to use the destructors to implement it.

See the solution

Now a quick discussion on destructors. The destructors do two things:

1. distinguish the different cases within a sum type; and
2. extract elements from each product type.

So for `MyList` the minimal set of destructors is `isEmpty`, which distinguishes `Empty` from `Pair`, and `head` and `tail`. The extractors are partial functions in the conceptual, not Scala, sense; they are only defined for a particular product type and throw an exception if used on a different case. You may have also noticed that the functions we passed to `fill` are exactly the destructors for natural numbers.

The destructors are another part of the duality between structural recursion and corecursion. Structural recursion is:

- defined by pattern matching on the constructors; and
- takes apart an algebraic data type into smaller pieces.

Structural corecursion instead is:

- defined by conditions on the input, which may use destructors; and
- build up an algebraic data type from smaller pieces.

One last thing before we leave `unfold`. If we look at the usual definition of `unfold` we'll probably find the following definition.

```
def unfold[A, B](in: A)(f: A => Option[(A, B)]): List[B]
```

This is equivalent to the definition we used, but a bit more compact in terms of the interface it presents. We used a more explicit definition that makes the structure of the method clearer.

2.5 Applications of Algebraic Data Types

We seen some examples of algebraic data types already. Some of the simplest are the basic enumeration, like

```
enum Permissions {  
    case User  
    case Moderator  
    case Admin  
}
```

and our old friend the `case class`

```
final case class Uri(protocol: String, host: String, port: Int, path:  
    String)
```

Those new to algebraic data types often don't realise how many other uses cases there are. We'll see combinator libraries, an extremely important use, in the next chapter. Here I want to give a few examples of finite state machines as another use case.

Finite state machines occur everywhere in programming. The state of a user interface component, such as open or closed, or visible or invisible, can be modelled as a finite state machine. That's probably not relevant to most Scala

programmers, so let's consider instead a distributed job server. The idea is here that users submit jobs to run on a cluster of computers. The supervisor is responsible for selecting a computer on which to run the job, monitoring it, and collecting the result on successful completion.

In a very simple system we might represent jobs as having four states:

1. Queued: the job is in the queue to be run.
2. Running: the job is running on a computer.
3. Completed: the job successfully finished and we have collected the result.
4. Failed: the job failed to run to completion.

When using an algebraic data type we're not restricted to a simple enumeration of states. We can also store data within the states. So, in our job control system, we could define the job states as follows:

```
import scala.concurrent.Future

enum Job[A] {
  case Queued(id: Int, name: String, job: () => A)
  case Running(id: Int, name: String, host: String, result: Future[A])
  case Completed(id: Int, name: String, result: A)
  case Failed(id: Int, name: String, reason: String)
}
```

If you look around the code you work with I expect you'll quickly find many other examples.

2.6 The Algebra of Algebraic Data Types

A question that sometimes comes up is where the “algebra” in algebraic data types comes from. I want to talk about this a little bit and show some of the algebraic manipulations that can be done on algebraic data types.

The term algebra is used in the sense of abstract algebra, an area of mathematics. Abstract algebra deals with algebraic data structures. An

algebraic structure consists of a set of values, operations on that set, and properties that those operations must maintain. An example is the set of integers, the operations addition and multiplication, and the familiar properties of these operations such as associativity, which says that $a + (b + c) = (a + b) + c$. The abstract in abstract algebra means that the field doesn't deal with concrete values like integers—that would be far too easy to understand—and instead with abstractions with wacky names like semigroup and monoid. The example of integers above is an instance of a ring. We'll see a lot more of these soon enough!

Algebraic data types also correspond to the algebraic structure called a ring. A ring has two operations, which are conventionally denoted with $+$ and \times . You'll perhaps guess that these correspond to sum and product types respectively, and you'd be absolutely correct. What about the properties of these operations? Well they are similar to what we know from basic algebra:

- $+$ and \times are associative, so $a + (b + c) = (a + b) + c$ and likewise for \times ;
- $a + b = b + a$, known as commutativity;
- there is an identity 0 such that $a + 0 = a$;
- there is an identity 1 such that $a \times 1 = a$;
- there is distribution, so that $a \times (b + c) = (a \times b) + (a \times c)$

So far, so abstract. Let's make it concrete by looking at actual examples in Scala.

Remember the algebraic data types work with types, so the operations $+$ and \times take types as parameters. So $\text{Int} \times \text{String}$ is equivalent to

```
final case class IntAndString(int: Int, string: String)
```

We can use tuples to avoid creating lots of names.

```
type IntAndString = (Int, String)
```

We can do the same thing for $+$. $\text{Int} + \text{String}$ is

```
enum IntOrString {
  case IsInt(int: Int)
  case IsString(string: String)
}
```

or just

```
type IntOrString = Either[Int, String]
```

Exercise: Identities

Can you work out which Scala type corresponds to the identity 1 for product types?

See the solution

What about the Scala type corresponding to the identity 0 for sum types?

See the solution

What about the distribution law? This allows us to manipulate algebraic data types to form equivalent, but perhaps more useful, representations. Consider this example of a user data type.

```
final case class Person(name: String, permissions: Permissions)
enum Permissions {
  case User
  case Moderator
}
```

Written in mathematical notation, this is

$$\text{Person} = \text{String} \times \text{Permissions}$$

$$\text{Permissions} = \text{User} + \text{Moderator}$$

Performing substitution gets us

$$\text{Person} = \text{String} \times (\text{User} + \text{Moderator})$$

Applying distribution results in

$$\text{Person} = (\text{String} \times \text{User}) + (\text{String} \times \text{Moderator})$$

which in Scala we can represent as

```
enum Person {  
    case User(name: String)  
    case Moderator(name: String)  
}
```

Is this representation more useful? I can't say without the context of where the code is being used. However I can say that knowing this manipulation is possible, and correct, is useful.

There is a lot more that could be said about algebraic data types, but at this point I feel we're really getting into the weeds. I'll finish up with a few pointers to other interesting facts:

- Exponential types exist. They are functions! A function $A \Rightarrow B$ is equivalent to b^a .
- Quotient types also exist, but they are a bit weird. Read up about them if you're interested.
- Another interesting algebraic manipulation is taking the derivative of an algebraic data type. This gives us a kind of iterator, known as a zipper, for that type.

2.7 Conclusions

We have covered a lot of material in this chapter. Let's recap the key points.

Algebraic data types allow us to express data types by combining existing data types with logical and and logical or. A logical and constructs a sum type while a logical or constructs a product type. Algebraic data types are the main way to represent data in Scala.

Structural recursion gives us a skeleton for transforming any given algebraic data type into any other type. Structural recursion can be abstracted into a `fold` method.

We use several reasoning principles to help us complete the problem specific parts of a structural recursion:

1. reasoning independently by case;
2. assuming recursion is correct; and
3. following the types.

Following the types is a very general strategy that is can be used in many other situations.

Structural corecursion gives us a skeleton for creating any given algebraic data type from any other type. Structural corecursion can be abstracted into an `unfold` method. When reasoning about structural corecursion we can reason as we would for an imperative loop, or, if the input is an algebraic data type, use the principles for reasoning about structural recursion.

Notice that the two main themes of functional programming—composition and reasoning—are both already apparent. Algebraic data types are compositional: we compose algebraic data types using sum and product. We've seen many reasoning principles in this chapter.

I haven't covered everything there is to know about algebraic data types; I think doing so would be a book in its own right. Below are some references that you might find useful if you want to dig in further, as well as some biographical remarks.

Algebraic data types are standard in introductory material on functional programming. Structural recursion is certainly extremely common in functional programming, but strangely seems to rarely be explicitly defined as I've done here. I learned about both from [How to Design Programs](#).

I'm not aware of any approachable yet thorough treatment of either algebraic data types or structural recursion. Both seem to have become assumed background of any researcher in the field of programming languages, and relatively recent work is caked in layers of mathematics and obtuse notation

that I find difficult reading. The infamous [Functional Programming with Bananas, Lenses, Envelopes and Barbed Wire](#) is an example of such work. I suspect the core ideas of both date back to at least the emergence of computability theory in the 1930s, well before any digital computers existed.

The earliest reference I've found to structural recursion is [Proving Properties of Programs by Structural Induction](#), which dates to 1969. Algebraic data types don't seem to have been fully developed, along with pattern matching, until [NPL](#) in 1977. NPL was quickly followed by the more influential language [Hope](#), which spread the concept to other programming languages.

Corecursion is a bit better documented in the contemporary literature. [How to Design Co-Programs](#) covers the main idea we have looked at here. [The Under-Appreciated Unfold](#) discusses uses of `unfold`.

[The Derivative of a Regular Type is its Type of One-Hole Contexts](#) describes the derivative of algebraic data types.

Chapter 3

Type Classes

Cats contains a wide variety of functional programming tools and allows developers to pick and choose the ones we want to use. The majority of these tools are delivered in the form of *type classes* that we can apply to existing Scala types.

Type classes are a programming pattern originating in Haskell¹. They allow us to extend existing libraries with new functionality, without using traditional inheritance, and without altering the original library source code.

In this chapter we will refresh our memory of type classes from Underscore's [Essential Scala](#) book, and take a first look at the Cats codebase. We will look at two example type classes—`Show` and `Eq`—using them to identify patterns that lay the foundations for the rest of the book.

We'll finish by tying type classes back into algebraic data types, pattern matching, value classes, and type aliases, presenting a structured approach to functional programming in Scala.

¹The word “class” doesn't strictly mean class in the Scala or Java sense.

3.1 Anatomy of a Type Class

There are three important components to the type class pattern: the *type class* itself, *instances* for particular types, and the methods that *use* type classes.

Type classes in Scala are implemented using *implicit values* and *parameters*, and optionally using *implicit classes*. Scala language constructs correspond to the components of type classes as follows:

- traits: type classes;
- implicit values: type class instances;
- implicit parameters: type class use; and
- implicit classes: optional utilities that make type classes easier to use.

Let's see how this works in detail.

3.1.1 The Type Class

A *type class* is an interface or API that represents some functionality we want to implement. In Scala a type class is represented by a trait with at least one type parameter. For example, we can represent generic “serialize to JSON” behaviour as follows:

```
// Define a very simple JSON AST
sealed trait Json
final case class JsObject(get: Map[String, Json]) extends Json
final case class JsString(get: String) extends Json
final case class JsNumber(get: Double) extends Json
case object JsNull extends Json

// The "serialize to JSON" behaviour is encoded in this trait
trait JsonWriter[A] {
  def write(value: A): Json
}
```

`JsonWriter` is our type class in this example, with `Json` and its subtypes providing supporting code. When we come to implement instances of

`JsonWriter`, the type parameter `A` will be the concrete type of data we are writing.

3.1.2 Type Class Instances

The *instances* of a type class provide implementations of the type class for specific types we care about, which can include types from the Scala standard library and types from our domain model.

In Scala we define instances by creating concrete implementations of the type class and tagging them with the `implicit` keyword:

```
final case class Person(name: String, email: String)

object JsonWriterInstances {
    implicit val stringWriter: JsonWriter[String] =
        new JsonWriter[String] {
            def write(value: String): Json =
                JsString(value)
        }

    implicit val personWriter: JsonWriter[Person] =
        new JsonWriter[Person] {
            def write(value: Person): Json =
                JsObject(Map(
                    "name" -> JsString(value.name),
                    "email" -> JsString(value.email)
                ))
        }

    // etc...
}
```

These are known as `implicit` values.

3.1.3 Type Class Use

A type class *use* is any functionality that requires a type class instance to work. In Scala this means any method that accepts instances of the type class as

implicit parameters.

Cats provides utilities that make type classes easier to use, and you will sometimes see these patterns in other libraries. There are two ways it does this: *Interface Objects* and *Interface Syntax*.

Interface Objects

The simplest way of creating an interface that uses a type class is to place methods in a singleton object:

```
object Json {
  def toJson[A](value: A)(implicit w: JsonWriter[A]): Json =
    w.write(value)
}
```

To use this object, we import any type class instances we care about and call the relevant method:

```
import JsonWriterInstances._

Json.toJson(Person("Dave", "dave@example.com"))
// res1: Json = JsObject(
//   get = Map(
//     "name" -> JsString(get = "Dave"),
//     "email" -> JsString(get = "dave@example.com")
//   )
// )
```

The compiler spots that we've called the `toJson` method without providing the implicit parameters. It tries to fix this by searching for type class instances of the relevant types and inserting them at the call site:

```
Json.toJson(Person("Dave", "dave@example.com"))(personWriter)
```

Interface Syntax

We can alternatively use *extension methods* to extend existing types with interface methods². Cats refers to this as “syntax” for the type class:

²You may occasionally see extension methods referred to as “type enrichment” or “pimping”. These are older terms that we don't use anymore.

```
object JsonSyntax {  
    implicit class JsonWriterOps[A](value: A) {  
        def toJson(implicit w: JsonWriter[A]): Json =  
            w.write(value)  
    }  
}
```

We use interface syntax by importing it alongside the instances for the types we need:

```
import JsonWriterInstances._  
import JsonSyntax._  
  
Person("Dave", "dave@example.com").toJson  
// res3: Json = JsObject(  
//   get = Map(  
//     "name" -> JsString(get = "Dave"),  
//     "email" -> JsString(get = "dave@example.com")  
//   )  
// )
```

Again, the compiler searches for candidates for the implicit parameters and fills them in for us:

```
Person("Dave", "dave@example.com").toJson(personWriter)
```

The *implicitly* Method

The Scala standard library provides a generic type class interface called `implicitly`. Its definition is very simple:

```
def implicitly[A](implicit value: A): A =  
    value
```

We can use `implicitly` to summon any value from implicit scope. We provide the type we want and `implicitly` does the rest:

```
import JsonWriterInstances._

implicitly[JsonWriter[String]]
// res5: JsonWriter[String] = repl.
MdocSession$MdocApp0$JsonWriterInstances$$anon$6@64790e62
```

Most type classes in Cats provide other means to summon instances. However, `implicitly` is a good fallback for debugging purposes. We can insert a call to `implicitly` within the general flow of our code to ensure the compiler can find an instance of a type class and ensure that there are no ambiguous implicit errors.

3.2 Working with Implicits

Working with type classes in Scala means working with implicit values and implicit parameters. There are a few rules we need to know to do this effectively.

3.2.1 Packaging Implicits

In a curious quirk of the language, any definitions marked `implicit` in Scala must be placed inside an object or trait rather than at the top level. In the example above we packaged our type class instances in an object called `JsonWriterInstances`. We could equally have placed them in a companion object to `JsonWriter`. Placing instances in a companion object to the type class has special significance in Scala because it plays into something called *implicit scope*.

3.2.2 Implicit Scope

As we saw above, the compiler searches for candidate type class instances by type. For example, in the following expression it will look for an instance of type `JsonWriter[String]`:

```
Json.toJson("A string!")
```

The places where the compiler searches for candidate instances is known as the *implicit scope*. The implicit scope applies at the call site; that is the point where we call a method with an implicit parameter. The implicit scope which roughly consists of:

- local or inherited definitions;
- imported definitions;
- definitions in the companion object of the type class or the parameter type (in this case `JsonWriter` or `String`).

Definitions are only included in implicit scope if they are tagged with the `implicit` keyword. Furthermore, if the compiler sees multiple candidate definitions, it fails with an *ambiguous implicit values* error:

```
implicit val writer1: JsonWriter[String] =
  JsonWriterInstances.stringWriter

implicit val writer2: JsonWriter[String] =
  JsonWriterInstances.stringWriter

Json.toJson("A string")
// error:
// Ambiguous given instances: both value writer1 in object MdocApp0
// and value writer2 in object MdocApp0 match type repl.MdocSession.
// MdocApp0.JsonWriter[String] of parameter w of method toJson in
// object Json
// Json.toJson(Option("A string"))
//                                     ^
```

The precise rules of implicit resolution are more complex than this, but the complexity is largely irrelevant for day-to-day use³. For our purposes, we can package type class instances in roughly four ways:

³If you're interested in the finer rules of implicit resolution in Scala, start by taking a look at [this Stack Overflow post on implicit scope](#) and [this blog post on implicit priority](#).

1. by placing them in an object such as `JsonWriterInstances`;
2. by placing them in a trait;
3. by placing them in the companion object of the type class;
4. by placing them in the companion object of the parameter type.

With option 1 we bring instances into scope by `importing` them. With option 2 we bring them into scope with inheritance. With options 3 and 4 instances are *always* in implicit scope, regardless of where we try to use them.

It is conventional to put type class instances in a companion object (option 3 and 4 above) if there is only one sensible implementation, or at least one implementation that is widely accepted as the default. This makes type class instances easier to use as no import is required to bring them into the implicit scope.

3.2.3 Recursive Implicit Resolution

The power of type classes and implicits lies in the compiler's ability to *combine* implicit definitions when searching for candidate instances. This is sometimes known as *type class composition*.

Earlier we insinuated that all type class instances are `implicit vals`. This was a simplification. We can actually define instances in two ways:

1. by defining concrete instances as `implicit vals` of the required type⁴;
2. by defining `implicit` methods to construct instances from other type class instances.

Why would we construct instances from other instances? As a motivational example, consider defining a `JsonWriter` for `Option`. We would need a `JsonWriter[Option[A]]` for every `A` we care about in our application. We could try to brute force the problem by creating a library of `implicit vals`:

⁴We can also use an `implicit object`, which provides the same thing as an `implicit val`.

```
implicit val optionIntWriter: JsonWriter[Option[Int]] =  
    ???  
  
implicit val optionPersonWriter: JsonWriter[Option[Person]] =  
    ???  
  
// and so on...
```

However, this approach clearly doesn't scale. We end up requiring two `implicit vals` for every type `A` in our application: one for `A` and one for `Option[A]`.

Fortunately, we can abstract the code for handling `Option[A]` into a common constructor based on the instance for `A`:

- if the option is `Some(aValue)`, write `aValue` using the writer for `A`;
- if the option is `None`, return `JsNull`.

Here is the same code written out as an `implicit def`:

```
implicit def optionWriter[A]  
  (implicit writer: JsonWriter[A]): JsonWriter[Option[A]] =  
  new JsonWriter[Option[A]] {  
    def write(option: Option[A]): Json =  
      option match {  
        case Some(aValue) => writer.write(aValue)  
        case None         => JsNull  
      }  
  }
```

This method *constructs* a `JsonWriter` for `Option[A]` by relying on an implicit parameter to fill in the `A`-specific functionality. When the compiler sees an expression like this:

```
Json.toJson(Option("A string"))
```

it searches for an implicit `JsonWriter[Option[String]]`. It finds the implicit method for `JsonWriter[Option[A]]`:

```
Json.toJson(Option("A string"))(optionWriter[String])
```

and recursively searches for a `JsonWriter[String]` to use as the parameter to `optionWriter`:

```
Json.toJson(Option("A string"))(optionWriter(stringWriter))
```

In this way, implicit resolution becomes a search through the space of possible combinations of implicit definitions, to find a combination that creates a type class instance of the correct overall type.

Implicit Conversions

When you create a type class instance constructor using an `implicit def`, be sure to mark the parameters to the method as `implicit` parameters. Without this keyword, the compiler won't be able to fill in the parameters during implicit resolution.

`implicit` methods with non-`implicit` parameters form a different Scala pattern called an *implicit conversion*. This is also different from the previous section on Interface Syntax, because in that case the `JsonWriter` is an implicit class with extension methods. Implicit conversion is an older programming pattern that is frowned upon in modern Scala code. Fortunately, the compiler will warn you when you do this. You have to manually enable implicit conversions by importing `scala.language.implicitConversions` in your file:

```
implicit def optionWriter[A]
  (writer: JsonWriter[A]): JsonWriter[Option[A]] =
  ???
// warning: implicit conversion method foo should be enabled
// by making the implicit value scala.language.
  implicitConversions visible.
// This can be achieved by adding the import clause 'import
  scala.language.implicitConversions'
// or by setting the compiler option -language:
  implicitConversions.
// See the Scaladoc for value scala.language.implicitConversions
  for a discussion
// why the feature should be explicitly enabled.
```

3.3 Exercise: Printable Library

Scala provides a `toString` method to let us convert any value to a `String`. However, this method comes with a few disadvantages: it is implemented for every type in the language, many implementations are of limited use, and we can't opt-in to specific implementations for specific types.

Let's define a `Printable` type class to work around these problems:

1. Define a type class `Printable[A]` containing a single method `format`. `format` should accept a value of type `A` and return a `String`.
2. Create an object `PrintableInstances` containing instances of `Printable` for `String` and `Int`.
3. Define an object `Printable` with two generic interface methods:
 - `format` accepts a value of type `A` and a `Printable` of the corresponding type. It uses the relevant `Printable` to convert the `A` to a `String`.
 - `print` accepts the same parameters as `format` and returns `Unit`. It prints the formatted `A` value to the console using `println`.

See the solution

Using the Library

The code above forms a general purpose printing library that we can use in multiple applications. Let's define an "application" now that uses the library.

First we'll define a data type to represent a well-known type of furry animal:

```
final case class Cat(name: String, age: Int, color: String)
```

Next we'll create an implementation of `Printable` for `Cat` that returns content in the following format:

```
NAME is a AGE year-old COLOR cat.
```

Finally, use the type class on the console or in a short demo app: create a `Cat` and print it to the console:

```
// Define a cat:  
val cat = Cat(/* ... */)  
  
// Print the cat!
```

See the solution

Better Syntax

Let's make our printing library easier to use by defining some extension methods to provide better syntax:

1. Create an object called `PrintableSyntax`.
2. Inside `PrintableSyntax` define an `implicit class PrintableOps[A]` to wrap up a value of type `A`.
3. In `PrintableOps` define the following methods:
 - `format` accepts an `implicit Printable[A]` and returns a `String` representation of the wrapped `A`;

- `print` accepts an implicit `Printable[A]` and returns `Unit`. It prints the wrapped `A` to the console.
4. Use the extension methods to print the example `Cat` you created in the previous exercise.

See the solution

3.4 Meet Cats

In the previous section we saw how to implement type classes in Scala. In this section we will look at how type classes are implemented in Cats.

Cats is written using a modular structure that allows us to choose which type classes, instances, and interface methods we want to use. Let's take a first look using `cats.Show` as an example.

`Show` is Cats' equivalent of the `Printable` type class we defined in the last section. It provides a mechanism for producing developer-friendly console output without using `toString`. Here's an abbreviated definition:

```
package cats

trait Show[A] {
  def show(value: A): String
}
```

3.4.1 Importing Type Classes

The type classes in Cats are defined in the `cats` package. We can import `Show` directly from this package:

```
import cats.Show
```

The companion object of every Cats type class has an `apply` method that locates an instance for any type we specify:

```
val showInt = Show.apply[Int]
// showInt: Show[Int] = cats.Show$$Lambda$15514/0
x00007f2d466ebd08@293222e6
```

Oops—that didn’t work! The `apply` method uses *implicits* to look up individual instances, so we’ll have to bring some instances into scope.

3.4.2 Importing Default Instances

The `cats.instances` package provides default instances for a wide variety of types. We can import these as shown in the table below. Each import provides instances of all Cats’ type classes for a specific parameter type:

- `cats.instances.int` provides instances for `Int`
- `cats.instances.string` provides instances for `String`
- `cats.instances.list` provides instances for `List`
- `cats.instances.option` provides instances for `Option`
- `cats.instances.all` provides all instances that are shipped out of the box with Cats

See the `cats.instances` package for a complete list of available imports.

Let’s import the instances of `Show` for `Int` and `String`:

```
import cats.Show
import cats.instances.int._    // for Show
import cats.instances.string._ // for Show

val showInt: Show[Int] = Show.apply[Int]
val showString: Show[String] = Show.apply[String]
```

That’s better! We now have access to two instances of `Show`, and can use them to print `Ints` and `Strings`:

```
val intAsString: String =
  showInt.show(123)
// intAsString: String = "123"

val stringAsString: String =
  showString.show("abc")
// stringAsString: String = "abc"
```

3.4.3 Importing Interface Syntax

We can make `Show` easier to use by importing the *interface syntax* from `cats.syntax.show`. This adds an extension method called `show` to any type for which we have an instance of `Show` in scope:

```
import cats.syntax.show._ // for show

val shownInt = 123.show
// shownInt: String = "123"

val shownString = "abc".show
// shownString: String = "abc"
```

Cats provides separate syntax imports for each type class. We will introduce these as we encounter them in later sections and chapters.

3.4.4 Importing All The Things!

In this book we will use specific imports to show you exactly which instances and syntax you need in each example. However, this doesn't add value in production code. It is simpler and faster to use the following imports:

- `import cats._` imports all of Cats' type classes in one go;
- `import cats.implicits._` imports all of the standard type class instances *and* all of the syntax in one go.

3.4.5 Defining Custom Instances

We can define an instance of `Show` simply by implementing the trait for a given type:

```
import java.util.Date

implicit val dateShow: Show[Date] =
  new Show[Date] {
    def show(date: Date): String =
      s"${date.getTime}ms since the epoch."
  }

new Date().show
// res1: String = "1696856506852ms since the epoch."
```

However, Cats also provides a couple of convenient methods to simplify the process. There are two construction methods on the companion object of `Show` that we can use to define instances for our own types:

```
object Show {
  // Convert a function to a `Show` instance:
  def show[A](f: A => String): Show[A] =
    ???

  // Create a `Show` instance from a `toString` method:
  def fromToString[A]: Show[A] =
    ???
}
```

These allow us to quickly construct instances with less ceremony than defining them from scratch:

```
implicit val dateShow: Show[Date] =
  Show.show(date => s"${date.getTime}ms since the epoch.")
```

As you can see, the code using construction methods is much terser than the code without. Many type classes in Cats provide helper methods like these for constructing instances, either from scratch or by transforming existing instances for other types.

3.4.6 Exercise: Cat Show

Re-implement the Cat application from the previous section using Show instead of Printable.

See the solution

3.5 Example: Eq

We will finish off this chapter by looking at another useful type class: [cats.Eq](#). Eq is designed to support *type-safe equality* and address annoyances using Scala's built-in == operator.

Almost every Scala developer has written code like this before:

```
List(1, 2, 3).map(Option(_)).filter(item => item == 1)
// warning: Option[Int] and Int are unrelated: they will most likely
// never compare equal
// res: List[Option[Int]] = List()
```

Ok, many of you won't have made such a simple mistake as this, but the principle is sound. The predicate in the filter clause always returns false because it is comparing an Int to an Option[Int].

This is programmer error—we should have compared item to Some(1) instead of 1. However, it's not technically a type error because == works for any pair of objects, no matter what types we compare. Eq is designed to add some type safety to equality checks and work around this problem.

3.5.1 Equality, Liberty, and Fraternity

We can use Eq to define type-safe equality between instances of any given type:

```
package cats

trait Eq[A] {
  def eqv(a: A, b: A): Boolean
  // other concrete methods based on eqv...
}
```

The interface syntax, defined in `cats.syntax.eq`, provides two methods for performing equality checks provided there is an instance `Eq[A]` in scope:

- `==` compares two objects for equality;
- `=!=` compares two objects for inequality.

3.5.2 Comparing Ints

Let's look at a few examples. First we import the type class:

```
import cats.Eq
```

Now let's grab an instance for `Int`:

```
import cats.instances.int._ // for Eq

val eqInt = Eq[Int]
```

We can use `eqInt` directly to test for equality:

```
eqInt.eqv(123, 123)
// res1: Boolean = true
eqInt.eqv(123, 234)
// res2: Boolean = false
```

Unlike Scala's `==` method, if we try to compare objects of different types using `eqv` we get a compile error:

```
eqInt.eqv(123, "234")
// error:
// Found:    ("234" : String)
// Required: Int
// val cat2 = Cat("Heathcliff", 32, "orange and black")
//                                     ^
```

We can also import the interface syntax in `cats.syntax.eq` to use the `==` and `=!=` methods:

```
import cats.syntax.eq._ // for == and !=

123 === 123
// res4: Boolean = true
123 =!= 234
// res5: Boolean = true
```

Again, comparing values of different types causes a compiler error:

```
123 === "123"
// error:
// Found:    ("123" : String)
// Required: Int
//      (cat1.name === cat2.name ) &&
//                                     ^
```

3.5.3 Comparing Options

Now for a more interesting example—`Option[Int]`. To compare values of type `Option[Int]` we need to import instances of `Eq` for `Option` as well as `Int`:

```
import cats.instances.int._    // for Eq
import cats.instances.option._ // for Eq
```

Now we can try some comparisons:

```
Some(1) === None
// error:
// value === is not a member of Some[Int] - did you mean Some[Int].==?
//   Eq.instance[Cat] { (cat1, cat2) =>
//   ^
```

We have received an error here because the types don't quite match up. We have `Eq` instances in scope for `Int` and `Option[Int]` but the values we are comparing are of type `Some[Int]`. To fix the issue we have to re-type the arguments as `Option[Int]`:

```
(Some(1) : Option[Int]) === (None : Option[Int])
// res8: Boolean = false
```

We can do this in a friendlier fashion using the `Option.apply` and `Option.empty` methods from the standard library:

```
Option(1) === Option.empty[Int]
// res9: Boolean = false
```

or using special syntax from `cats.syntax.option`:

```
import cats.syntax.option._ // for some and none

1.some === none[Int]
// res10: Boolean = false
1.some != none[Int]
// res11: Boolean = true
```

3.5.4 Comparing Custom Types

We can define our own instances of `Eq` using the `Eq.instance` method, which accepts a function of type `(A, A) => Boolean` and returns an `Eq[A]`:

```
import java.util.Date
import cats.instances.long._ // for Eq
```

```
implicit val dateEq: Eq[Date] =  
  Eq.instance[Date] { (date1, date2) =>  
    date1.getTime === date2.getTime  
  }  
  
val x = new Date() // now  
val y = new Date() // a bit later than now  
  
x === x  
// res12: Boolean = true  
x === y  
// res13: Boolean = true
```

3.5.5 Exercise: Equality, Liberty, and Felinity

Implement an instance of `Eq` for our running `Cat` example:

```
final case class Cat(name: String, age: Int, color: String)
```

Use this to compare the following pairs of objects for equality and inequality:

```
val cat1 = Cat("Garfield", 38, "orange and black")  
val cat2 = Cat("Heathcliff", 33, "orange and black")  
  
val optionCat1 = Option(cat1)  
val optionCat2 = Option.empty[Cat]
```

See the solution

3.6 Controlling Instance Selection

When working with type classes we must consider two issues that control instance selection:

- What is the relationship between an instance defined on a type and its subtypes?

For example, if we define a `JsonWriter[Option[Int]]`, will the expression `Json.toJson(Some(1))` select this instance? (Remember that `Some` is a subtype of `Option`).

- How do we choose between type class instances when there are many available?

What if we define two `JsonWriters` for `Person`? When we write `Json.toJson(aPerson)`, which instance is selected?

3.6.1 Variance

When we define type classes we can add variance annotations to the type parameter to affect the variance of the type class and the compiler's ability to select instances during implicit resolution.

To recap Essential Scala, variance relates to subtypes. We say that `B` is a subtype of `A` if we can use a value of type `B` anywhere we expect a value of type `A`.

Co- and contravariance annotations arise when working with type constructors. For example, we denote covariance with a `+` symbol:

```
trait F[+A] // the "+" means "covariant"
```

Covariance

Covariance means that the type `F[B]` is a subtype of the type `F[A]` if `B` is a subtype of `A`. This is useful for modelling many types, including collections like `List` and `Option`:

```
trait List[+A]
trait Option[+A]
```

The covariance of Scala collections allows us to substitute collections of one type with a collection of a subtype in our code. For example, we can use a `List[Circle]` anywhere we expect a `List[Shape]` because `Circle` is a subtype of `Shape`:

```
sealed trait Shape
case class Circle(radius: Double) extends Shape

val circles: List[Circle] = ???
val shapes: List[Shape] = circles
```

Generally speaking, covariance is used for outputs: data that we can later get out of a container type such as `List`, or otherwise returned by some method.

Contravariance

What about contravariance? We write contravariant type constructors with a `-` symbol like this:

```
trait F[-A]
```

Perhaps confusingly, contravariance means that the type `F[B]` is a subtype of `F[A]` if `A` is a subtype of `B`. This is useful for modelling types that represent inputs, like our `JsonWriter` type class above:

```
trait JsonWriter[-A] {
  def write(value: A): Json
}
```

Let's unpack this a bit further. Remember that variance is all about the ability to substitute one value for another. Consider a scenario where we have two values, one of type `Shape` and one of type `Circle`, and two `JsonWriters`, one for `Shape` and one for `Circle`:

```
val shape: Shape = ???
val circle: Circle = ???

val shapeWriter: JsonWriter[Shape] = ???
val circleWriter: JsonWriter[Circle] = ???

def format[A](value: A, writer: JsonWriter[A]): Json =
  writer.write(value)
```

Now ask yourself the question: “Which combinations of value and writer can I pass to `format`?” We can write a `Circle` with either writer because all `Circles`

are Shapes. Conversely, we can't write a Shape with `circleWriter` because not all Shapes are Circles.

This relationship is what we formally model using contravariance. `JsonWriter[Shape]` is a subtype of `JsonWriter[Circle]` because `Circle` is a subtype of `Shape`. This means we can use `shapeWriter` anywhere we expect to see a `JsonWriter[Circle]`.

Invariance

Invariance is the easiest situation to describe. It's what we get when we don't write a + or - in a type constructor:

```
trait F[A]
```

This means the types `F[A]` and `F[B]` are never subtypes of one another, no matter what the relationship between `A` and `B`. This is the default semantics for Scala type constructors.

When the compiler searches for an implicit it looks for one matching the type *or subtype*. Thus we can use variance annotations to control type class instance selection to some extent.

There are two issues that tend to arise. Let's imagine we have an algebraic data type like:

```
sealed trait A
final case object B extends A
final case object C extends A
```

The issues are:

1. Will an instance defined on a supertype be selected if one is available?
For example, can we define an instance for `A` and have it work for values of type `B` and `C`?
2. Will an instance for a subtype be selected in preference to that of a supertype. For instance, if we define an instance for `A` and `B`, and we have a value of type `B`, will the instance for `B` be selected in preference to `A`?

It turns out we can't have both at once. The three choices give us behaviour as follows:

Type Class Variance	Invariant	Covariant	Contravariant
Supertype instance used?	No	No	Yes
More specific type preferred?	No	Yes	No

It's clear there is no perfect system. Cats prefers to use invariant type classes. This allows us to specify more specific instances for subtypes if we want. It does mean that if we have, for example, a value of type `Some[Int]`, our type class instance for `Option` will not be used. We can solve this problem with a type annotation like `Some(1): Option[Int]` or by using “smart constructors” like the `Option.apply`, `Option.empty`, `some`, and `none` methods we saw in Section 3.5.3.

3.7 Summary

In this chapter we took a first look at type classes. We implemented our own `Printable` type class using plain Scala before looking at two examples from Cats—`Show` and `Eq`.

We saw the components that make up a type class:

- A trait, which is the type class
- Type class instances, which are implicit values.
- Type class usage, which uses implicit parameters.

We have also seen the general patterns in Cats type classes:

- The type classes themselves are generic traits in the `cats` package.
- Each type class has a companion object with, an `apply` method for materializing instances, one or more *construction* methods for creating instances, and a collection of other relevant helper methods.

- Default instances are provided via objects in the `cats.instances` package, and are organized by parameter type rather than by type class.
- Many type classes have syntax provided via the `cats.syntax` package.

In the remaining chapters of Part I we will look at several broad and powerful type classes—Semigroup, Monoid, Functor, Monad, Semigroupal, Applicative, Traverse, and more. In each case we will learn what functionality the type class provides, the formal rules it follows, and how it is implemented in Cats. Many of these type classes are more abstract than Show or Eq. While this makes them harder to learn, it makes them far more useful for solving general problems in our code.

Chapter 4

Monoids and Semigroups

In this section we explore our first type classes, **monoid** and **semigroup**. These allow us to add or combine values. There are instances for `Ints`, `Strings`, `Lists`, `Options`, and many more. Let's start by looking at a few simple types and operations to see what common principles we can extract.

Integer addition

Addition of `Ints` is a binary operation that is *closed*, meaning that adding two `Ints` always produces another `Int`:

```
2 + 1
// res0: Int = 3
```

There is also the *identity* element `0` with the property that `a + 0 == 0 + a == a` for any `Int a`:

```
2 + 0
// res1: Int = 2

0 + 2
// res2: Int = 2
```

There are also other properties of addition. For instance, it doesn't matter in

what order we add elements because we always get the same result. This is a property known as *associativity*:

```
(1 + 2) + 3
// res3: Int = 6

1 + (2 + 3)
// res4: Int = 6
```

Integer multiplication

The same properties for addition also apply for multiplication, provided we use 1 as the identity instead of 0:

```
1 * 3
// res5: Int = 3

3 * 1
// res6: Int = 3
```

Multiplication, like addition, is associative:

```
(1 * 2) * 3
// res7: Int = 6

1 * (2 * 3)
// res8: Int = 6
```

String and sequence concatenation

We can also add Strings, using string concatenation as our binary operator:

```
"One" ++ "two"
// res9: String = "Onetwo"
```

and the empty string as the identity:

```

    "" ++ "Hello"
// res10: String = "Hello"

"Hello" ++ ""
// res11: String = "Hello"

```

Once again, concatenation is associative:

```

("One" ++ "Two") ++ "Three"
// res12: String = "OneTwoThree"

"One" ++ ("Two" ++ "Three")
// res13: String = "OneTwoThree"

```

Note that we used `++` above instead of the more usual `+` to suggest a parallel with sequences. We can do the same with other types of sequence, using concatenation as the binary operator and the empty sequence as our identity.

4.1 Definition of a Monoid

We've seen a number of "addition" scenarios above each with an associative binary addition and an identity element. It will be no surprise to learn that this is a monoid. Formally, a monoid for a type `A` is:

- an operation `combine` with type `(A, A) => A`
- an element `empty` of type `A`

This definition translates nicely into Scala code. Here is a simplified version of the definition from Cats:

```

trait Monoid[A] {
  def combine(x: A, y: A): A
  def empty: A
}

```

In addition to providing the `combine` and `empty` operations, monoids must formally obey several *laws*. For all values `x`, `y`, and `z`, in `A`, `combine` must be associative and `empty` must be an identity element:

```

def associativeLaw[A](x: A, y: A, z: A)
    (implicit m: Monoid[A]): Boolean = {
  m.combine(x, m.combine(y, z)) ==
  m.combine(m.combine(x, y), z)
}

def identityLaw[A](x: A)
    (implicit m: Monoid[A]): Boolean = {
  (m.combine(x, m.empty) == x) &&
  (m.combine(m.empty, x) == x)
}

```

Integer subtraction, for example, is not a monoid because subtraction is not associative:

```

(1 - 2) - 3
// res14: Int = -4

1 - (2 - 3)
// res15: Int = 2

```

In practice we only need to think about laws when we are writing our own Monoid instances. Unlawful instances are dangerous because they can yield unpredictable results when used with the rest of Cats' machinery. Most of the time we can rely on the instances provided by Cats and assume the library authors know what they're doing.

4.2 Definition of a Semigroup

A semigroup is just the `combine` part of a monoid, without the `empty` part. While many semigroups are also monoids, there are some data types for which we cannot define an `empty` element. For example, we have just seen that sequence concatenation and integer addition are monoids. However, if we restrict ourselves to non-empty sequences and positive integers, we are no longer able to define a sensible `empty` element. Cats has a `NonEmptyList` data type that has an implementation of `Semigroup` but no implementation of `Monoid`.

A more accurate (though still simplified) definition of Cats' `Monoid` is:

```
trait Semigroup[A] {  
    def combine(x: A, y: A): A  
}  
  
trait Monoid[A] extends Semigroup[A] {  
    def empty: A  
}
```

We'll see this kind of inheritance often when discussing type classes. It provides modularity and allows us to re-use behaviour. If we define a `Monoid` for a type `A`, we get a `Semigroup` for free. Similarly, if a method requires a parameter of type `Semigroup[B]`, we can pass a `Monoid[B]` instead.

4.3 Exercise: The Truth About Monoids

We've seen a few examples of monoids but there are plenty more to be found. Consider `Boolean`. How many monoids can you define for this type? For each monoid, define the `combine` and `empty` operations and convince yourself that the monoid laws hold. Use the following definitions as a starting point:

```
trait Semigroup[A] {  
    def combine(x: A, y: A): A  
}  
  
trait Monoid[A] extends Semigroup[A] {  
    def empty: A  
}  
  
object Monoid {  
    def apply[A](implicit monoid: Monoid[A]) =  
        monoid  
}
```

See the solution

4.4 Exercise: All Set for Monoids

What monoids and semigroups are there for sets?

See the solution

4.5 Monoids in Cats

Now we've seen what monoids are, let's look at their implementation in Cats. Once again we'll look at the three main aspects of the implementation: the *type class*, the *instances*, and the *interface*.

4.5.1 The Monoid Type Class

The monoid type class is `cats.kernel.Monoid`, which is aliased as `cats.Monoid`. `Monoid` extends `cats.kernel.Semigroup`, which is aliased as `cats.Semigroup`. When using Cats we normally import type classes from the `cats` package:

```
import cats.Monoid
import cats.Semigroup
```

Cats Kernel?

Cats Kernel is a subproject of Cats providing a small set of typeclasses for libraries that don't require the full Cats toolbox. While these core type classes are technically defined in the `cats.kernel` package, they are all aliased to the `cats` package so we rarely need to be aware of the distinction.

The Cats Kernel type classes covered in this book are `Eq`, `Semigroup`, and `Monoid`. All the other type classes we cover are part of the main Cats project and are defined directly in the `cats` package.

4.5.2 Monoid Instances

Monoid follows the standard Cats pattern for the user interface: the companion object has an `apply` method that returns the type class instance for a particular type. For example, if we want the monoid instance for `String`, and we have the correct implicits in scope, we can write the following:

```
import cats.Monoid
import cats.instances.string._ // for Monoid

Monoid[String].combine("Hi ", "there")
// res0: String = "Hi there"
Monoid[String].empty
// res1: String = ""
```

which is equivalent to:

```
Monoid.apply[String].combine("Hi ", "there")
// res2: String = "Hi there"
Monoid.apply[String].empty
// res3: String = ""
```

As we know, `Monoid` extends `Semigroup`. If we don't need `empty` we can equivalently write:

```
import cats.Semigroup

Semigroup[String].combine("Hi ", "there")
// res4: String = "Hi there"
```

The type class instances for `Monoid` are organised under `cats.instances` in the standard way described in Chapter 3.4.2. For example, if we want to pull in instances for `Int` we import from `cats.instances.int`:

```
import cats.Monoid
import cats.instances.int._ // for Monoid

Monoid[Int].combine(32, 10)
```

```
// res5: Int = 42
```

Similarly, we can assemble a `Monoid[Option[Int]]` using instances from `cats.instances.int` and `cats.instances.option`:

```
import cats.Monoid
import cats.instances.int._      // for Monoid
import cats.instances.option._ // for Monoid

val a = Option(22)
// a: Option[Int] = Some(value = 22)
val b = Option(20)
// b: Option[Int] = Some(value = 20)

Monoid[Option[Int]].combine(a, b)
// res6: Option[Int] = Some(value = 42)
```

Refer back to Chapter 3.4.2 for a more comprehensive list of imports.

As always, unless we have a good reason to import individual instances, we can just import everything.

```
import cats._
import cats.implicits._
```

4.5.3 Monoid Syntax

Cats provides syntax for the `combine` method in the form of the `|+|` operator. Because `combine` technically comes from `Semigroup`, we access the syntax by importing from `cats.syntax.semigroup`:

```
import cats.instances.string._ // for Monoid
import cats.syntax.semigroup._ // for |+|

val stringResult = "Hi " |+| "there" |+| Monoid[String].empty
// stringResult: String = "Hi there"

import cats.instances.int._ // for Monoid
```

```
val intResult = 1 |+| 2 |+| Monoid[Int].empty
// intResult: Int = 3
```

4.5.4 Exercise: Adding All The Things

The cutting edge *SuperAdder v3.5a-32* is the world's first choice for adding together numbers. The main function in the program has signature `def add(items: List[Int]): Int`. In a tragic accident this code is deleted! Rewrite the method and save the day!

See the solution

Well done! SuperAdder's market share continues to grow, and now there is demand for additional functionality. People now want to add `List[Option[Int]]`. Change `add` so this is possible. The SuperAdder code base is of the highest quality, so make sure there is no code duplication!

See the solution

SuperAdder is entering the POS (point-of-sale, not the other POS) market. Now we want to add up orders:

```
case class Order(totalCost: Double, quantity: Double)
```

We need to release this code really soon so we can't make any modifications to `add`. Make it so!

See the solution

4.6 Applications of Monoids

We now know what a monoid is—an abstraction of the concept of adding or combining—but where is it useful? Here are a few big ideas where monoids play a major role. These are explored in more detail in case studies later in the book.

4.6.1 Big Data

In big data applications like Spark and Hadoop we distribute data analysis over many machines, giving fault tolerance and scalability. This means each machine will return results over a portion of the data, and we must then combine these results to get our final result. In the vast majority of cases this can be viewed as a monoid.

If we want to calculate how many total visitors a web site has received, that means calculating an `Int` on each portion of the data. We know the monoid instance of `Int` is addition, which is the right way to combine partial results.

If we want to find out how many unique visitors a website has received, that's equivalent to building a `Set[User]` on each portion of the data. We know the monoid instance for `Set` is the set union, which is the right way to combine partial results.

If we want to calculate 99% and 95% response times from our server logs, we can use a data structure called a `QTree` for which there is a monoid.

Hopefully you get the idea. Almost every analysis that we might want to do over a large data set is a monoid, and therefore we can build an expressive and powerful analytics system around this idea. This is exactly what Twitter's Algebird and Summingbird projects have done. We explore this idea further in the map-reduce case study in Section 11.

4.6.2 Distributed Systems

In a distributed system, different machines may end up with different views of data. For example, one machine may receive an update that other machines did not receive. We would like to reconcile these different views, so every machine has the same data if no more updates arrive. This is called *eventual consistency*.

A particular class of data types support this reconciliation. These data types are called commutative replicated data types (CRDTs). The key operation is the ability to merge two data instances, with a result that captures all the information in both instances. This operation relies on having a monoid instance. We explore this idea further in the CRDT case study.

4.6.3 Monoids in the Small

The two examples above are cases where monoids inform the entire system architecture. There are also many cases where having a monoid around makes it easier to write a small code fragment. We'll see lots of examples in the case studies in this book.

4.7 Summary

We hit a big milestone in this chapter—we covered our first type classes with fancy functional programming names:

- a `Semigroup` represents an addition or combination operation;
- a `Monoid` extends a `Semigroup` by adding an identity or “zero” element.

We can use `Semigroups` and `Monoids` by importing three things: the type classes themselves, the instances for the types we care about, and the semigroup syntax to give us the `|+|` operator:

```
import cats.Monoid
import cats.instances.string._ // for Monoid
import cats.syntax.semigroup._ // for |+|  
  
"Scala" |+| " with " |+| "Cats"
// res0: String = "Scala with Cats"
```

With the correct instances in scope, we can set about adding anything we want:

```
import cats.instances.int._    // for Monoid
import cats.instances.option._ // for Monoid  
  
Option(1) |+| Option(2)
// res1: Option[Int] = Some(value = 3)  
  
import cats.instances.map._ // for Monoid
```

```

val map1 = Map("a" -> 1, "b" -> 2)
val map2 = Map("b" -> 3, "d" -> 4)

map1 |+| map2
// res2: Map[String, Int] = Map("b" -> 5, "d" -> 4, "a" -> 1)

import cats.instances.tuple._ // for Monoid

val tuple1 = ("hello", 123)
val tuple2 = ("world", 321)

tuple1 |+| tuple2
// res3: Tuple2[String, Int] = ("helloworld", 444)

```

We can also write generic code that works with any type for which we have an instance of Monoid:

```

def addAll[A](values: List[A])
  (implicit monoid: Monoid[A]): A =
  values.foldRight(monoid.empty)(_ |+| _)

addAll(List(1, 2, 3))
// res4: Int = 6
addAll(List(None, Some(1), Some(2)))
// res5: Option[Int] = Some(value = 3)

```

Monoids are a great gateway to Cats. They're easy to understand and simple to use. However, they're just the tip of the iceberg in terms of the abstractions Cats enables us to make. In the next chapter we'll look at *functors*, the type class personification of the beloved `map` method. That's where the fun really begins!

Chapter 5

Functors

In this chapter we will investigate **functors**, an abstraction that allows us to represent sequences of operations within a context such as a `List`, an `Option`, or any one of a thousand other possibilities. Functors on their own aren't so useful, but special cases of functors, such as **monads** and **applicative functors**, are some of the most commonly used abstractions in Cats.

5.1 Examples of Functors

Informally, a functor is anything with a `map` method. You probably know lots of types that have this: `Option`, `List`, and `Either`, to name a few.

We typically first encounter `map` when iterating over `Lists`. However, to understand functors we need to think of the method in another way. Rather than traversing the list, we should think of it as transforming all of the values inside in one go. We specify the function to apply, and `map` ensures it is applied to every item. The values change but the structure of the list (the number of elements and their order) remains the same:

```
List(1, 2, 3).map(n => n + 1)
// res0: List[Int] = List(2, 3, 4)
```

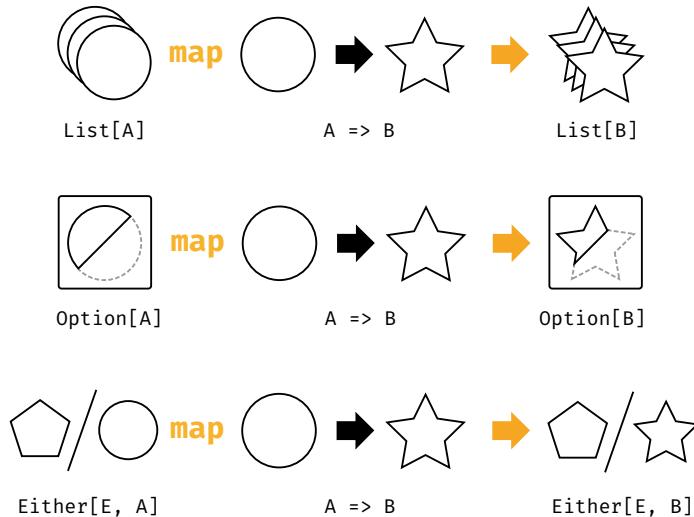

Figure 5.1: Type chart: mapping over List, Option, and Either

Similarly, when we `map` over an `Option`, we transform the contents but leave the `Some` or `None` context unchanged. The same principle applies to `Either` with its `Left` and `Right` contexts. This general notion of transformation, along with the common pattern of type signatures shown in Figure 5.1, is what connects the behaviour of `map` across different data types.

Because `map` leaves the structure of the context unchanged, we can call it repeatedly to sequence multiple computations on the contents of an initial data structure:

```
List(1, 2, 3).
  map(n => n + 1).
  map(n => n * 2).
  map(n => s"${n}!")
// res1: List[String] = List("4!", "6!", "8!")
```

We should think of `map` not as an iteration pattern, but as a way of sequencing computations on values ignoring some complication dictated by the relevant data type:

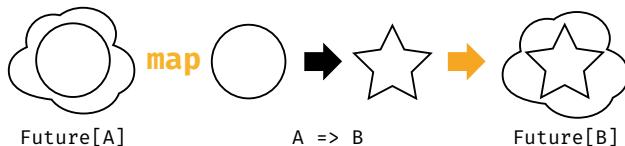

Figure 5.2: Type chart: mapping over a Future

- `Option`—the value may or may not be present;
- `Either`—there may be a value or an error;
- `List`—there may be zero or more values.

5.2 More Examples of Functors

The `map` methods of `List`, `Option`, and `Either` apply functions eagerly. However, the idea of sequencing computations is more general than this. Let's investigate the behaviour of some other functors that apply the pattern in different ways.

Futures

`Future` is a functor that sequences asynchronous computations by queueing them and applying them as their predecessors complete. The type signature of its `map` method, shown in Figure 5.2, has the same shape as the signatures above. However, the behaviour is very different.

When we work with a `Future` we have no guarantees about its internal state. The wrapped computation may be ongoing, complete, or rejected. If the `Future` is complete, our mapping function can be called immediately. If not, some underlying thread pool queues the function call and comes back to it later. We don't know *when* our functions will be called, but we do know *what order* they will be called in. In this way, `Future` provides the same sequencing behaviour seen in `List`, `Option`, and `Either`:

```
import scala.concurrent.{Future, Await}
import scala.concurrent.ExecutionContext.Implicits.global
import scala.concurrent.duration._

val future: Future[String] =
  Future(123).
    map(n => n + 1).
    map(n => n * 2).
    map(n => s"${n}!")

Await.result(future, 1.second)
// res2: String = "248!"
```

Futures and Referential Transparency

Note that Scala's Futures aren't a great example of pure functional programming because they aren't *referentially transparent*. Future always computes and caches a result and there's no way for us to tweak this behaviour. This means we can get unpredictable results when we use Future to wrap side-effecting computations. For example:

```
import scala.util.Random

val future1 = {
    // Initialize Random with a fixed seed:
    val r = new Random(0L)

    // nextInt has the side-effect of moving to
    // the next random number in the sequence:
    val x = Future(r.nextInt())

    for {
        a <- x
        b <- x
    } yield (a, b)
}

val future2 = {
    val r = new Random(0L)

    for {
        a <- Future(r.nextInt())
        b <- Future(r.nextInt())
    } yield (a, b)
}

val result1 = Await.result(future1, 1.second)
// result1: Tuple2[Int, Int] = (-1155484576, -1155484576)
val result2 = Await.result(future2, 1.second)
// result2: Tuple2[Int, Int] = (-1155484576, -723955400)
```

Ideally we would like `result1` and `result2` to contain the same value. However, the computation for `future1` calls `nextInt` once and the computation for `future2` calls it twice. Because `nextInt` returns a different result every time we get a different result in each case.

This kind of discrepancy makes it hard to reason about programs involving Futures and side-effects. There also are other problematic aspects of Future's behaviour, such as the way it always starts computations immediately rather than allowing the user to dictate when the program should run. For more information see [this excellent Reddit](#)

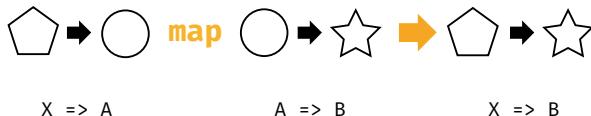

Figure 5.3: Type chart: mapping over a Function1

[answer](#) by Rob Norris.

When we look at Cats Effect we'll see that the `I0` type solves these problems.

If Future isn't referentially transparent, perhaps we should look at another similar data-type that is. You should recognise this one...

Functions (?!)

It turns out that single argument functions are also functors. To see this we have to tweak the types a little. A function $A \Rightarrow B$ has two type parameters: the parameter type A and the result type B . To coerce them to the correct shape we can fix the parameter type and let the result type vary:

- start with $X \Rightarrow A$;
- supply a function $A \Rightarrow B$;
- get back $X \Rightarrow B$.

If we alias $X \Rightarrow A$ as `MyFunc[A]`, we see the same pattern of types we saw with the other examples in this chapter. We also see this in Figure 5.3:

- start with `MyFunc[A]`;
- supply a function $A \Rightarrow B$;
- get back `MyFunc[B]`.

In other words, “mapping” over a `Function1` is function composition:

```

import cats.instances.function._ // for Functor
import cats.syntax.functor._   // for map

val func1: Int => Double =
  (x: Int) => x.toDouble

val func2: Double => Double =
  (y: Double) => y * 2

(func1 map func2)(1)      // composition using map
// res3: Double = 2.0      // composition using map
(func1 andThen func2)(1) // composition using andThen
// res4: Double = 2.0 // composition using andThen
func2(func1(1))          // composition written out by hand
// res5: Double = 2.0

```

How does this relate to our general pattern of sequencing operations? If we think about it, function composition *is* sequencing. We start with a function that performs a single operation and every time we use `map` we append another operation to the chain. Calling `map` doesn't actually *run* any of the operations, but if we can pass an argument to the final function all of the operations are run in sequence. We can think of this as lazily queueing up operations similar to `Future`:

```

val func =
  ((x: Int) => x.toDouble).
    map(x => x + 1).
    map(x => x * 2).
    map(x => s"${x}!")

func(123)
// res6: String = "248.0!"

```

Partial Unification

For the above examples to work, in versions of Scala before 2.13, we need to add the following compiler option to `build.sbt`:

```
scalacOptions += "-Ypartial-unification"
```

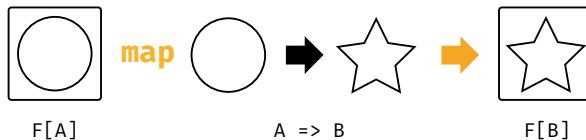

Figure 5.4: Type chart: generalised functor map

otherwise we'll get a compiler error:

```
func1.map(func2)
// <console>: error: value map is not a member of Int => Double
//           func1.map(func2)
^
```

We'll look at why this happens in detail in Section 5.8.

5.3 Definition of a Functor

Every example we've looked at so far is a functor: a class that encapsulates sequencing computations. Formally, a functor is a type $F[A]$ with an operation map with type $(A \Rightarrow B) \Rightarrow F[B]$. The general type chart is shown in Figure 5.4.

Cats encodes `Functor` as a type class, `cats.Functor`, so the method looks a little different. It accepts the initial $F[A]$ as a parameter alongside the transformation function. Here's a simplified version of the definition:

```
package cats

trait Functor[F[_]] {
  def map[A, B](fa: F[A])(f: A => B): F[B]
}
```

If you haven't seen syntax like $F[_]$ before, it's time to take a brief detour to discuss *type constructors* and *higher kinded types*.

Functor Laws

Functors guarantee the same semantics whether we sequence many small operations one by one, or combine them into a larger function before mapping. To ensure this is the case the following laws must hold:

Identity: calling `map` with the identity function is the same as doing nothing:

```
fa.map(a => a) == fa
```

Composition: mapping with two functions `f` and `g` is the same as mapping with `f` and then mapping with `g`:

```
fa.map(g(f(_))) == fa.map(f).map(g)
```

5.4 Aside: Higher Kinds and Type Constructors

Kinds are like types for types. They describe the number of “holes” in a type. We distinguish between regular types that have no holes and “type constructors” that have holes we can fill to produce types.

For example, `List` is a type constructor with one hole. We fill that hole by specifying a parameter to produce a regular type like `List[Int]` or `List[A]`. The trick is not to confuse type constructors with generic types. `List` is a type constructor, `List[A]` is a type:

```
List    // type constructor, takes one parameter
List[A] // type, produced by applying a type parameter
```

There's a close analogy here with functions and values. Functions are “value constructors”—they produce values when we supply parameters:

```
math.abs    // function, takes one parameter
math.abs(x) // value, produced by applying a value parameter
```

In Scala we declare type constructors using underscores. This specifies how many “holes” the type constructor has. However, to use them we refer to just the name.

```
// Declare F using underscores:
def myMethod[F[_]] = {

  // Reference F without underscores:
  val functor = Functor.apply[F]

  // ...
}
```

This is analogous to specifying function parameter types. When we declare a parameter we also give its type. However, to use them we refer to just the name.

```
// Declare f specifying parameter types
def f(x: Int): Int =
  // Reference x without type
  x * 2
```

Armed with this knowledge of type constructors, we can see that the Cats definition of `Functor` allows us to create instances for any single-parameter type constructor, such as `List`, `Option`, `Future`, or a type alias such as `MyFunc`.

Language Feature Imports

In versions of Scala before 2.13 we need to “enable” the higher kinded type language feature, to suppress warnings from the compiler, whenever we declare a type constructor with `A[_]` syntax. We can either do this with a “language import” as above:

```
import scala.language.higherKinds
```

or by adding the following to `scalacOptions` in `build.sbt`:

```
scalacOptions += "-language:higherKinds"
```

In practice we find the `scalacOptions` flag to be the simpler of the two options.

5.5 Functors in Cats

Let's look at the implementation of functors in Cats. We'll examine the same aspects we did for monoids: the *type class*, the *instances*, and the *syntax*.

5.5.1 The Functor Type Class and Instances

The functor type class is `cats.Functor`. We obtain instances using the standard `Functor.apply` method on the companion object. As usual, default instances are arranged by type in the `cats.instances` package:

```
import cats.Functor
import cats.instances.list._    // for Functor
import cats.instances.option._ // for Functor

val list1 = List(1, 2, 3)
// list1: List[Int] = List(1, 2, 3)
val list2 = Functor[List].map(list1)(_ * 2)
// list2: List[Int] = List(2, 4, 6)

val option1 = Option(123)
// option1: Option[Int] = Some(value = 123)
val option2 = Functor[Option].map(option1)(_.toString)
// option2: Option[String] = Some(value = "123")
```

`Functor` provides a method called `lift`, which converts a function of type `A => B` to one that operates over a functor and has type `F[A] => F[B]`:

```
val func = (x: Int) => x + 1
// func: Function1[Int, Int] = repl.
MdocSession$MdocApp0$$Lambda$16937/0x00007f2d468c9810@1123924e

val liftedFunc = Functor[Option].lift(func)
// liftedFunc: Function1[Option[Int], Option[Int]] = cats.
```

```
Functor$$Lambda$16938/0x00007f2d468f38a0@59d38783
liftedFunc(Option(1))
// res1: Option[Int] = Some(value = 2)
```

The `as` method is the other method you are likely to use. It replaces `with` with `value` inside the `Functor` with the given value.

```
Functor[List].as(list1, "As")
// res2: List[String] = List("As", "As", "As")
```

5.5.2 Functor Syntax

The main method provided by the syntax for `Functor` is `map`. It's difficult to demonstrate this with `Options` and `Lists` as they have their own built-in `map` methods and the Scala compiler will always prefer a built-in method over an extension method. We'll work around this with two examples.

First let's look at mapping over functions. Scala's `Function1` type doesn't have a `map` method (it's called `andThen` instead) so there are no naming conflicts:

```
import cats.instances.function._ // for Functor
import cats.syntax.functor._    // for map

val func1 = (a: Int) => a + 1
val func2 = (a: Int) => a * 2
val func3 = (a: Int) => s"${a}!"
val func4 = func1.map(func2).map(func3)

func4(123)
// res3: String = "248!"
```

Let's look at another example. This time we'll abstract over functors so we're not working with any particular concrete type. We can write a method that applies an equation to a number no matter what functor context it's in:

```

def doMath[F[_]](start: F[Int])
    (implicit functor: Functor[F]): F[Int] =
  start.map(n => n + 1 * 2)

import cats.instances.option._ // for Functor
import cats.instances.list._ // for Functor

doMath(Option(20))
// res4: Option[Int] = Some(value = 22)
doMath(List(1, 2, 3))
// res5: List[Int] = List(3, 4, 5)

```

To illustrate how this works, let's take a look at the definition of the `map` method in `cats.syntax.functor`. Here's a simplified version of the code:

```

implicit class FunctorOps[F[_], A](src: F[A]) {
  def map[B](func: A => B)
    (implicit functor: Functor[F]): F[B] =
  functor.map(src)(func)
}

```

The compiler can use this extension method to insert a `map` method wherever no built-in `map` is available:

```
foo.map(value => value + 1)
```

Assuming `foo` has no built-in `map` method, the compiler detects the potential error and wraps the expression in a `FunctorOps` to fix the code:

```
new FunctorOps(foo).map(value => value + 1)
```

The `map` method of `FunctorOps` requires an implicit `Functor` as a parameter. This means this code will only compile if we have a `Functor` for `F` in scope. If we don't, we get a compiler error:

```

final case class Box[A](value: A)

val box = Box[Int](123)

```

```
box.map(value => value + 1)
// error:
// value map is not a member of repl.MdocSession.MdocApp0.Box[Int]
```

The `as` method is also available as syntax.

```
List(1, 2, 3).as("As")
// res7: List[String] = List("As", "As", "As")
```

5.5.3 Instances for Custom Types

We can define a functor simply by defining its `map` method. Here's an example of a Functor for `Option`, even though such a thing already exists in `cats.instances`. The implementation is trivial—we simply call `Option`'s `map` method:

```
implicit val optionFunctor: Functor[Option] =
  new Functor[Option] {
    def map[A, B](value: Option[A])(func: A => B): Option[B] =
      value.map(func)
  }
```

Sometimes we need to inject dependencies into our instances. For example, if we had to define a custom Functor for `Future` (another hypothetical example—`Cats` provides one in `cats.instances.future`) we would need to account for the `implicit ExecutionContext` parameter on `future.map`. We can't add extra parameters to `functor.map` so we have to account for the dependency when we create the instance:

```
import scala.concurrent.{Future, ExecutionContext}

implicit def futureFunctor
  (implicit ec: ExecutionContext): Functor[Future] =
  new Functor[Future] {
    def map[A, B](value: Future[A])(func: A => B): Future[B] =
      value.map(func)
  }
```

Whenever we summon a Functor for Future, either directly using Functor .apply or indirectly via the map extension method, the compiler will locate futureFunctor by implicit resolution and recursively search for an ExecutionContext at the call site. This is what the expansion might look like:

```
// We write this:  
Functor[Future]  
  
// The compiler expands to this first:  
Functor[Future](futureFunctor)  
  
// And then to this:  
Functor[Future](futureFunctor(executionContext))
```

5.5.4 Exercise: Branching out with Functors

Write a Functor for the following binary tree data type. Verify that the code works as expected on instances of Branch and Leaf:

```
sealed trait Tree[+A]  
  
final case class Branch[A](left: Tree[A], right: Tree[A])  
  extends Tree[A]  
  
final case class Leaf[A](value: A) extends Tree[A]
```

See the solution

5.6 Contravariant and Invariant Function

As we have seen, we can think of Functor's map method as "appending" a transformation to a chain. We're now going to look at two other type classes, one representing *prepend*ing operations to a chain, and one representing building a *bidirectional* chain of operations. These are called *contravariant* and *invariant functors* respectively.

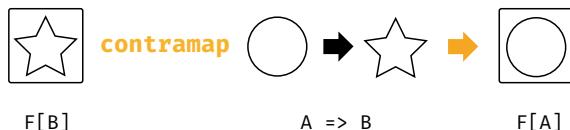

Figure 5.5: Type chart: the `contramap` method

This Section is Optional!

You don't need to know about contravariant and invariant functors to understand monads, which are the most important pattern in this book and the focus of the next chapter. However, contravariant and invariant do come in handy in our discussion of `Semigroupal` and `Applicative` in Chapter 8.

If you want to move on to monads now, feel free to skip straight to Chapter 6. Come back here before you read Chapter 8.

5.6.1 Contravariant Functors and the `contramap` Method

The first of our type classes, the *contravariant functor*, provides an operation called `contramap` that represents “prepending” an operation to a chain. The general type signature is shown in Figure 5.5.

The `contramap` method only makes sense for data types that represent *transformations*. For example, we can't define `contramap` for an `Option` because there is no way of feeding a value in an `Option[B]` backwards through a function `A => B`. However, we can define `contramap` for the `Printable` type class we discussed in Chapter 3:

```
trait Printable[A] {
  def format(value: A): String
}
```

A `Printable[A]` represents a transformation from `A` to `String`. Its `contramap`

method accepts a function `func` of type `B => A` and creates a new `Printable[B]`:
]:

```
trait Printable[A] {  
    def format(value: A): String  
  
    def contramap[B](func: B => A): Printable[B] =  
        ???  
    }  
  
    def format[A](value: A)(implicit p: Printable[A]): String =  
        p.format(value)
```

5.6.1.1 Exercise: Showing off with Contramap

Implement the `contramap` method for `Printable` above. Start with the following code template and replace the `???` with a working method body:

```
trait Printable[A] {  
    def format(value: A): String  
  
    def contramap[B](func: B => A): Printable[B] =  
        new Printable[B] {  
            def format(value: B): String =  
                ???  
        }  
    }
```

If you get stuck, think about the types. You need to turn `value`, which is of type `B`, into a `String`. What functions and methods do you have available and in what order do they need to be combined?

See the solution

For testing purposes, let's define some instances of `Printable` for `String` and `Boolean`:

```

implicit val stringPrintable: Printable[String] =
  new Printable[String] {
    def format(value: String): String =
      s"${value}"
  }

implicit val booleanPrintable: Printable[Boolean] =
  new Printable[Boolean] {
    def format(value: Boolean): String =
      if(value) "yes" else "no"
  }

format("hello")
// res2: String = "hello"
format(true)
// res3: String = "yes"

```

Now define an instance of `Printable` for the following `Box` case class. You'll need to write this as an `implicit def` as described in Section 3.2.3:

```
final case class Box[A](value: A)
```

Rather than writing out the complete definition from scratch (`new Printable[Box]` etc...), create your instance from an existing instance using `contramap`.

Your instance should work as follows:

```

format(Box("hello world"))
// res4: String = "hello world"
format(Box(true))
// res5: String = "yes"

```

If we don't have a `Printable` for the type inside the `Box`, calls to `format` should fail to compile:

```

format(Box(123))
// error:
// No given instance of type repl.MdocSession.MdocApp1.Printable[repl.
  MdocSession.MdocApp1.Box[Int]] was found for parameter p of
  method format in object MdocApp1.

```

```
// I found:
//
//      repl.MdocSession.MdocApp1.boxPrintable[A](
//          /* missing */summon[repl.MdocSession.MdocApp1.Printable[A]])
//
// But no implicit values were found that match type repl.MdocSession.
// MdocApp1.Printable[A].
// def encode[A](value: A)(implicit c: Codec[A]): String =
//
```

See the solution

5.6.2 Invariant functors and the `imap` method

Invariant functors implement a method called `imap` that is informally equivalent to a combination of `map` and `contramap`. If `map` generates new type class instances by appending a function to a chain, and `contramap` generates them by prepending an operation to a chain, `imap` generates them via a pair of bidirectional transformations.

The most intuitive examples of this are a type class that represents encoding and decoding as some data type, such as Play JSON's [Format](#) and scodec's [Codec](#). We can build our own `Codec` by enhancing `Printable` to support encoding and decoding to/from a `String`:

```
trait Codec[A] {
  def encode(value: A): String
  def decode(value: String): A
  def imap[B](dec: A => B, enc: B => A): Codec[B] = ???
}

def encode[A](value: A)(implicit c: Codec[A]): String =
  c.encode(value)

def decode[A](value: String)(implicit c: Codec[A]): A =
  c.decode(value)
```

The type chart for `imap` is shown in Figure 5.6. If we have a `Codec[A]` and a pair of functions `A => B` and `B => A`, the `imap` method creates a `Codec[B]`:

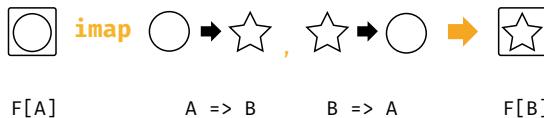

Figure 5.6: Type chart: the `imap` method

As an example use case, imagine we have a basic `Codec[String]`, whose `encode` and `decode` methods both simply return the value they are passed:

```

implicit val stringCodec: Codec[String] =
  new Codec[String] {
    def encode(value: String): String = value
    def decode(value: String): String = value
  }
  
```

We can construct many useful `Codecs` for other types by building off of `stringCodec` using `imap`:

```

implicit val intCodec: Codec[Int] =
  stringCodec imap (_.toInt, _.toString)

implicit val booleanCodec: Codec[Boolean] =
  stringCodec imap (_.toBoolean, _.toString)
  
```

Coping with Failure

Note that the `decode` method of our `Codec` type class doesn't account for failures. If we want to model more sophisticated relationships we can move beyond functors to look at *lenses* and *optics*.

Optics are beyond the scope of this book. However, Julien Truffaut's library [Monocle](#) provides a great starting point for further investigation.

5.6.2.1 Transformative Thinking with `imap`

Implement the `imap` method for `Codec` above.

See the solution

Demonstrate your `imap` method works by creating a Codec for `Double`.

See the solution

Finally, implement a Codec for the following `Box` type:

```
final case class Box[A](value: A)
```

See the solution

Your instances should work as follows:

```
encode(123.4)
// res11: String = "123.4"
decode[Double]("123.4")
// res12: Double = 123.4

encode(Box(123.4))
// res13: String = "123.4"
decode[Box[Double]]("123.4")
// res14: Box[Double] = Box(value = 123.4)
```

What's With the Names?

What's the relationship between the terms “contravariance”, “invariance”, and “covariance” and these different kinds of functor?

If you recall from Section 3.6.1, variance affects subtyping, which is essentially our ability to use a value of one type in place of a value of another type without breaking the code.

Subtyping can be viewed as a conversion. If `B` is a subtype of `A`, we can always convert a `B` to an `A`.

Equivalently we could say that `B` is a subtype of `A` if there exists a function `B => A`. A standard covariant functor captures exactly this. If `F` is a covariant functor, wherever we have an `F[B]` and a conversion `B => A` we can always convert to an `F[A]`.

A contravariant functor captures the opposite case. If F is a contravariant functor, whenever we have a $F[A]$ and a conversion $B \Rightarrow A$ we can convert to an $F[B]$.

Finally, invariant functors capture the case where we can convert from $F[A]$ to $F[B]$ via a function $A \Rightarrow B$ and vice versa via a function $B \Rightarrow A$.

5.7 Contravariant and Invariant in Cats

Let's look at the implementation of contravariant and invariant functors in Cats, provided by the `cats.Contravariant` and `cats.Invariant` type classes. Here's a simplified version of the code:

```
trait Contravariant[F[_]] {
  def contramap[A, B](fa: F[A])(f: B => A): F[B]
}

trait Invariant[F[_]] {
  def imap[A, B](fa: F[A])(f: A => B)(g: B => A): F[B]
}
```

5.7.1 Contravariant in Cats

We can summon instances of `Contravariant` using the `Contravariant.apply` method. Cats provides instances for data types that consume parameters, including `Eq`, `Show`, and `Function1`. Here's an example:

```
import cats.Contravariant
import cats.Show
import cats.instances.string._

val showString = Show[String]

val showSymbol = Contravariant[Show].
  contramap(showString)((sym: Symbol) => s"'${sym.name}'")

showSymbol.show(Symbol("dave"))
```

```
// res1: String = "'dave"
```

More conveniently, we can use `cats.syntax.contravariant`, which provides a `contramap` extension method:

```
import cats.syntax.contravariant._ // for contramap

showString
  .contramap[Symbol](sym => s"'${sym.name}'")
  .show(Symbol("dave"))
// res2: String = "'dave"
```

5.7.2 Invariant in Cats

Among other types, Cats provides an instance of `Invariant` for `Monoid`. This is a little different from the `Codec` example we introduced in Section 5.6.2. If you recall, this is what `Monoid` looks like:

```
package cats

trait Monoid[A] {
  def empty: A
  def combine(x: A, y: A): A
}
```

Imagine we want to produce a `Monoid` for Scala's `Symbol` type. Cats doesn't provide a `Monoid` for `Symbol` but it does provide a `Monoid` for a similar type: `String`. We can write our new semigroup with an `empty` method that relies on the empty `String`, and a `combine` method that works as follows:

1. accept two `Symbols` as parameters;
2. convert the `Symbols` to `Strings`;
3. combine the `Strings` using `Monoid[String]`;
4. convert the result back to a `Symbol`.

We can implement `combine` using `imap`, passing functions of type `String => Symbol` and `Symbol => String` as parameters. Here's the code, written out using the `imap` extension method provided by `cats.syntax.invariant`:

```

import cats.Monoid
import cats.instances.string._ // for Monoid
import cats.syntax.invariant._ // for imap
import cats.syntax.semigroup._ // for |+| 

implicit val symbolMonoid: Monoid[Symbol] =
  Monoid[String].imap(Symbol.apply)(_.name)

Monoid[Symbol].empty
// res3: Symbol = '

Symbol("a") |+| Symbol("few") |+| Symbol("words")
// res4: Symbol = 'afewwords'

```

5.8 Aside: Partial Unification

In Section 5.2 we saw a functor instance for `Function1`.

```

import cats.Functor
import cats.instances.function._ // for Functor
import cats.syntax.functor._    // for map

val func1 = (x: Int)    => x.toDouble
val func2 = (y: Double) => y * 2

val func3 = func1.map(func2)
// func3: Function1[Int, Double] = scala.Function1$$Lambda$16920/0
// x00007f2d468f8000@257b5f49

```

`Function1` has two type parameters (the function argument and the result type):

```

trait Function1[-A, +B] {
  def apply(arg: A): B
}

```

However, `Functor` accepts a type constructor with one parameter:

```
trait Functor[F[_]] {  
    def map[A, B](fa: F[A])(func: A => B): F[B]  
}
```

The compiler has to fix one of the two parameters of `Function1` to create a type constructor of the correct kind to pass to `Functor`. It has two options to choose from:

```
type F[A] = Int => A  
type F[A] = A => Double
```

We know that the former of these is the correct choice. However the compiler doesn't understand what the code means. Instead it relies on a simple rule, implementing what is called "partial unification".

The partial unification in the Scala compiler works by fixing type parameters from left to right. In the above example, the compiler fixes the `Int` in `Int => Double` and looks for a `Functor` for functions of type `Int => ?`:

```
type F[A] = Int => A  
  
val functor = Functor[F]
```

This left-to-right elimination works for a wide variety of common scenarios, including `Functors` for types such as `Function1` and `Either`:

```
val either: Either[String, Int] = Right(123)  
// either: Either[String, Int] = Right(value = 123)  
  
either.map(_ + 1)  
// res0: Either[String, Int] = Right(value = 124)
```

Partial unification is the default behaviour in Scala 2.13. In earlier versions of Scala we need to add the `-Ypartial-unification` compiler flag. In sbt we would add the compiler flag in `build.sbt`:

```
scalacOptions += "-Ypartial-unification"
```

The rationale behind this change is discussed in [SI-2712](#).

5.8.1 Limitations of Partial Unification

There are situations where left-to-right elimination is not the correct choice. One example is the `Or` type in [Scalactic](#), which is a conventionally left-biased equivalent of `Either`:

```
type PossibleResult = ActualResult Or Error
```

Another example is the Contravariant functor for `Function1`.

While the covariant Functor for `Function1` implements `andThen`-style left-to-right function composition, the Contravariant functor implements `compose`-style right-to-left composition. In other words, the following expressions are all equivalent:

```
val func3a: Int => Double =
  a => func2(func1(a))

val func3b: Int => Double =
  func2.compose(func1)

// Hypothetical example. This won't actually compile:
val func3c: Int => Double =
  func2.contramap(func1)
```

If we try this for real, however, our code won't compile:

```
import cats.syntax.contravariant._ // for contramap

val func3c = func2.contramap(func1)
// error:
// value contramap is not a member of Double => Double.
// An extension method was tried, but could not be fully constructed:
//      cats.syntax.contravariant.toContravariantOps[[R] => Double =>
R, A]()
```

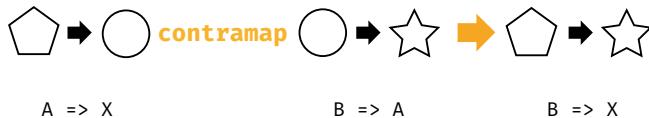

Figure 5.7: Type chart: contramapping over a Function1

```
//      repl.MdocSession.MdocApp.func2()
//      cats.instances.function.catsStdContravariantForFunction1[R])
// val func3c = func2.contramap(func1)
//           ^^^^^^^^^^^^^^
```

The problem here is that the Contravariant for Function1 fixes the return type and leaves the parameter type varying, requiring the compiler to eliminate type parameters from right to left, as shown below and in Figure 5.7:

```
type F[A] = A => Double
```

The compiler fails simply because of its left-to-right bias. We can prove this by creating a type alias that flips the parameters on Function1:

```
type <=[B, A] = A => B
type F[A] = Double <= A
```

If we re-type func2 as an instance of `<=`, we reset the required order of elimination and we can call `contramap` as desired:

```
val func2b: Double <= Double = func2

val func3c = func2b.contramap(func1)
// func3c: Function1[Int, Double] = scala.Function1$$Lambda$16920/0
// x00007f2d468f8000@8610b54
```

The difference between `func2` and `func2b` is purely syntactic—both refer to the same value and the type aliases are otherwise completely compatible.

Incredibly, however, this simple rephrasing is enough to give the compiler the hint it needs to solve the problem.

It is rare that we have to do this kind of right-to-left elimination. Most multi-parameter type constructors are designed to be right-biased, requiring the left-to-right elimination that is supported by the compiler out of the box. However, it is useful to know about this quirk of elimination order in case you ever come across an odd scenario like the one above.

5.9 Summary

Functors represent sequencing behaviours. We covered three types of functor in this chapter:

- Regular covariant Functors, with their `map` method, represent the ability to apply functions to a value in some context. Successive calls to `map` apply these functions in *sequence*, each accepting the result of its predecessor as a parameter.
- Contravariant functors, with their `contramap` method, represent the ability to “prepend” functions to a function-like context. Successive calls to `contramap` sequence these functions in the opposite order to `map`.
- Invariant functors, with their `imap` method, represent bidirectional transformations.

Regular Functors are by far the most common of these type classes, but even then it is rare to use them on their own. Functors form a foundational building block of several more interesting abstractions that we use all the time. In the following chapters we will look at two of these abstractions: *monads* and *applicative functors*.

Functors for collections are extremely important, as they transform each element independently of the rest. This allows us to parallelise or distribute

transformations on large collections, a technique leveraged heavily in “map-reduce” frameworks like [Hadoop](#). We will investigate this approach in more detail in the map-reduce case study later in Section 11.

The `Contravariant` and `Invariant` type classes are less widely applicable but are still useful for building data types that represent transformations. We will revisit them to discuss the `Semigroupal` type class later in Chapter 8.

Chapter 6

Monads

Monads are one of the most common abstractions in Scala. Many Scala programmers quickly become intuitively familiar with monads, even if we don't know them by name.

Informally, a monad is anything with a constructor and a `flatMap` method. All of the functors we saw in the last chapter are also monads, including `Option`, `List`, and `Future`. We even have special syntax to support monads: for comprehensions. However, despite the ubiquity of the concept, the Scala standard library lacks a concrete type to encompass “things that can be `flatMap`ped”. This type class is one of the benefits brought to us by Cats.

In this chapter we will take a deep dive into monads. We will start by motivating them with a few examples. We'll proceed to their formal definition and their implementation in Cats. Finally, we'll tour some interesting monads that you may not have seen, providing introductions and examples of their use.

6.1 What is a Monad?

This is the question that has been posed in a thousand blog posts, with explanations and analogies involving concepts as diverse as cats, Mexican

food, space suits full of toxic waste, and monoids in the category of endofunctors (whatever that means). We're going to solve the problem of explaining monads once and for all by stating very simply:

A monad is a mechanism for *sequencing computations*.

That was easy! Problem solved, right? But then again, last chapter we said functors were a control mechanism for exactly the same thing. Ok, maybe we need some more discussion...

In Section 5.1 we said that functors allow us to sequence computations ignoring some complication. However, functors are limited in that they only allow this complication to occur once at the beginning of the sequence. They don't account for further complications at each step in the sequence.

This is where monads come in. A monad's `flatMap` method allows us to specify what happens next, taking into account an intermediate complication. The `flatMap` method of `Option` takes intermediate `Options` into account. The `flatMap` method of `List` handles intermediate `Lists`. And so on. In each case, the function passed to `flatMap` specifies the application-specific part of the computation, and `flatMap` itself takes care of the complication allowing us to `flatMap` again. Let's ground things by looking at some examples.

Options

`Option` allows us to sequence computations that may or may not return values. Here are some examples:

```
def parseInt(str: String): Option[Int] =  
  scala.util.Try(str.toInt).toOption  
  
def divide(a: Int, b: Int): Option[Int] =  
  if(b == 0) None else Some(a / b)
```

Each of these methods may "fail" by returning `None`. The `flatMap` method allows us to ignore this when we sequence operations:

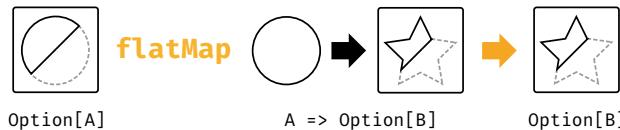

Figure 6.1: Type chart: flatMap for Option

```
def stringDivideBy(aStr: String, bStr: String): Option[Int] =  
  parseInt(aStr).flatMap { aNum =>  
    parseInt(bStr).flatMap { bNum =>  
      divide(aNum, bNum)  
    }  
  }
```

The semantics are:

- the first call to `parseInt` returns a `None` or a `Some`;
- if it returns a `Some`, the `flatMap` method calls our function and passes us the integer `aNum`;
- the second call to `parseInt` returns a `None` or a `Some`;
- if it returns a `Some`, the `flatMap` method calls our function and passes us `bNum`;
- the call to `divide` returns a `None` or a `Some`, which is our result.

At each step, `flatMap` chooses whether to call our function, and our function generates the next computation in the sequence. This is shown in Figure 6.1.

The result of the computation is an `Option`, allowing us to call `flatMap` again and so the sequence continues. This results in the fail-fast error handling behaviour that we know and love, where a `None` at any step results in a `None` overall:

```
stringDivideBy("6", "2")  
// res0: Option[Int] = Some(value = 3)  
stringDivideBy("6", "0")  
// res1: Option[Int] = None  
stringDivideBy("6", "foo")
```

```
// res2: Option[Int] = None
stringDivideBy("bar", "2")
// res3: Option[Int] = None
```

Every monad is also a functor (see below for proof), so we can rely on both `flatMap` and `map` to sequence computations that do and don't introduce a new monad. Plus, if we have both `flatMap` and `map` we can use for comprehensions to clarify the sequencing behaviour:

```
def stringDivideBy(aStr: String, bStr: String): Option[Int] =
  for {
    aNum <- parseInt(aStr)
    bNum <- parseInt(bStr)
    ans  <- divide(aNum, bNum)
  } yield ans
```

Lists

When we first encounter `flatMap` as budding Scala developers, we tend to think of it as a pattern for iterating over `Lists`. This is reinforced by the syntax of for comprehensions, which look very much like imperative for loops:

```
for {
  x <- (1 to 3).toList
  y <- (4 to 5).toList
} yield (x, y)
// res5: List[Tuple2[Int, Int]] = List(
//   (1, 4),
//   (1, 5),
//   (2, 4),
//   (2, 5),
//   (3, 4),
//   (3, 5)
// )
```

However, there is another mental model we can apply that highlights the monadic behaviour of `List`. If we think of `Lists` as sets of intermediate results, `flatMap` becomes a construct that calculates permutations and combinations.

For example, in the for comprehension above there are three possible values of `x` and two possible values of `y`. This means there are six possible values of

(x , y). flatMap is generating these combinations from our code, which states the sequence of operations:

- get x
- get y
- create a tuple (x , y)

Futures

Future is a monad that sequences computations without worrying that they may be asynchronous:

```
import scala.concurrent.Future
import scala.concurrent.ExecutionContext.Implicits.global

def doSomethingLongRunning: Future[Int] = ???
def doSomethingElseLongRunning: Future[Int] = ???

def doSomethingVeryLongRunning: Future[Int] =
  for {
    result1 <- doSomethingLongRunning
    result2 <- doSomethingElseLongRunning
  } yield result1 + result2
```

Again, we specify the code to run at each step, and flatMap takes care of all the horrifying underlying complexities of thread pools and schedulers.

If you've made extensive use of Future, you'll know that the code above is running each operation *in sequence*. This becomes clearer if we expand out the for comprehension to show the nested calls to flatMap:

```
def doSomethingVeryLongRunning: Future[Int] =
  doSomethingLongRunning.flatMap { result1 =>
    doSomethingElseLongRunning.map { result2 =>
      result1 + result2
    }
  }
```

Each Future in our sequence is created by a function that receives the result from a previous Future. In other words, each step in our computation can only

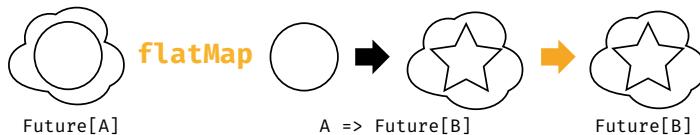

Figure 6.2: Type chart: flatMap for Future

start once the previous step is finished. This is born out by the type chart for flatMap in Figure 6.2, which shows the function parameter of type $A \Rightarrow \text{Future}[B]$.

We can run futures in parallel, of course, but that is another story and shall be told another time. Monads are all about sequencing.

6.1.1 Definition of a Monad

While we have only talked about flatMap above, monadic behaviour is formally captured in two operations:

- pure, of type $A \Rightarrow F[A]$;
- flatMap¹, of type $(F[A], A \Rightarrow F[B]) \Rightarrow F[B]$.

pure abstracts over constructors, providing a way to create a new monadic context from a plain value. flatMap provides the sequencing step we have already discussed, extracting the value from a context and generating the next context in the sequence. Here is a simplified version of the Monad type class in Cats:

```

trait Monad[F[_]] {
  def pure[A](value: A): F[A]

  def flatMap[A, B](value: F[A])(func: A => F[B]): F[B]
}
  
```

¹In some libraries and languages, notably Scalaz and Haskell, pure is referred to as point or return and flatMap is referred to as bind or $>>=$. This is purely a difference in terminology. We'll use the term flatMap for compatibility with Cats and the Scala standard library.

```
}
```

Monad Laws

pure and flatMap must obey a set of laws that allow us to sequence operations freely without unintended glitches and side-effects:

Left identity: calling pure and transforming the result with func is the same as calling func:

```
pure(a).flatMap(func) == func(a)
```

Right identity: passing pure to flatMap is the same as doing nothing:

```
m.flatMap(pure) == m
```

Associativity: flatMapping over two functions f and g is the same as flatMapping over f and then flatMapping over g:

```
m.flatMap(f).flatMap(g) == m.flatMap(x => f(x).flatMap(g))
```

6.1.2 Exercise: Getting Func-y

Every monad is also a functor. We can define map in the same way for every monad using the existing methods, flatMap and pure:

```
trait Monad[F[_]] {
  def pure[A](a: A): F[A]

  def flatMap[A, B](value: F[A])(func: A => F[B]): F[B]

  def map[A, B](value: F[A])(func: A => B): F[B] =
    ???
}
```

Try defining `map` yourself now.

See the solution

6.2 Monads in Cats

It's time to give monads our standard Cats treatment. As usual we'll look at the type class, instances, and syntax.

6.2.1 The Monad Type Class

The monad type class is `cats.Monad`. `Monad` extends two other type classes: `FlatMap`, which provides the `flatMap` method, and `Applicative`, which provides `pure`. `Applicative` also extends `Functor`, which gives every `Monad` a `map` method as we saw in the exercise above. We'll discuss `Applicatives` in Chapter 8.

Here are some examples using `pure` and `flatMap`, and `map` directly:

```
import cats.Monad
import cats.instances.option._ // for Monad
import cats.instances.list._ // for Monad

val opt1 = Monad[Option].pure(3)
// opt1: Option[Int] = Some(value = 3)
val opt2 = Monad[Option].flatMap(opt1)(a => Some(a + 2))
// opt2: Option[Int] = Some(value = 5)
val opt3 = Monad[Option].map(opt2)(a => 100 * a)
// opt3: Option[Int] = Some(value = 500)

val list1 = Monad[List].pure(3)
// list1: List[Int] = List(3)
val list2 = Monad[List].
  flatMap(List(1, 2, 3))(a => List(a, a*10))
// list2: List[Int] = List(1, 10, 2, 20, 3, 30)
val list3 = Monad[List].map(list2)(a => a + 123)
// list3: List[Int] = List(124, 133, 125, 143, 126, 153)
```

`Monad` provides many other methods, including all of the methods from `Functor`. See the [scaladoc](#) for more information.

6.2.2 Default Instances

Cats provides instances for all the monads in the standard library (`Option`, `List`, `Vector` and so on) via `cats.instances`:

```
import cats.instances.option._ // for Monad

Monad[Option].flatMap(Option(1))(a => Option(a*2))
// res0: Option[Int] = Some(value = 2)

import cats.instances.list._ // for Monad

Monad[List].flatMap(List(1, 2, 3))(a => List(a, a*10))
// res1: List[Int] = List(1, 10, 2, 20, 3, 30)

import cats.instances.vector._ // for Monad

Monad[Vector].flatMap(Vector(1, 2, 3))(a => Vector(a, a*10))
// res2: Vector[Int] = Vector(1, 10, 2, 20, 3, 30)
```

Cats also provides a `Monad` for `Future`. Unlike the methods on the `Future` class itself, the `pure` and `flatMap` methods on the monad can't accept implicit `ExecutionContext` parameters (because the parameters aren't part of the definitions in the `Monad` trait). To work around this, Cats requires us to have an `ExecutionContext` in scope when we summon a `Monad` for `Future`:

```
import cats.instances.future._ // for Monad
import scala.concurrent._
import scala.concurrent.duration._

val fm = Monad[Future]
// error:
// No given instance of type cats.Monad.concurrent.Future was found
// for parameter instance of method apply in object Monad.
// I found:
//
//      cats.instances.future.catsStdInstancesForFuture(
//          /* missing */summon[concurrent.ExecutionContext])
//
// But no implicit values were found that match type concurrent.
```

```
ExecutionContext.
// def sumSquare[F[_]: Monad](a: F[Int], b: F[Int]): F[Int] =
//
```

Bringing the `ExecutionContext` into scope fixes the implicit resolution required to summon the instance:

```
import scala.concurrent.ExecutionContext.Implicits.global

val fm = Monad[Future]
// fm: Monad[[T >: Nothing <: Any] => Future[T]] = cats.instances.
    FutureInstances$$anon$1@42dfbcab
```

The `Monad` instance uses the captured `ExecutionContext` for subsequent calls to `pure` and `flatMap`:

```
val future = fm.flatMap(fm.pure(1))(x => fm.pure(x + 2))

Await.result(future, 1.second)
// res4: Int = 3
```

In addition to the above, Cats provides a host of new monads that we don't have in the standard library. We'll familiarise ourselves with some of these in a moment.

6.2.3 Monad Syntax

The syntax for monads comes from three places:

- `cats.syntax.flatMap` provides syntax for `flatMap`;
- `cats.syntax.functor` provides syntax for `map`;
- `cats.syntax.applicative` provides syntax for `pure`.

In practice it's often easier to import everything in one go from `cats.implicits`. However, we'll use the individual imports here for clarity.

We can use `pure` to construct instances of a monad. We'll often need to specify the type parameter to disambiguate the particular instance we want.

```

import cats.instances.option._    // for Monad
import cats.instances.list._     // for Monad
import cats.syntax.applicative._ // for pure

1.pure[Option]
// res5: Option[Int] = Some(value = 1)
1.pure[List]
// res6: List[Int] = List(1)

```

It's difficult to demonstrate the `flatMap` and `map` methods directly on Scala monads like `Option` and `List`, because they define their own explicit versions of those methods. Instead we'll write a generic function that performs a calculation on parameters that come wrapped in a monad of the user's choice:

```

import cats.Monad
import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatMap

def sumSquare[F[_]: Monad](a: F[Int], b: F[Int]): F[Int] =
  a.flatMap(x => b.map(y => x*x + y*y))

import cats.instances.option._ // for Monad
import cats.instances.list._   // for Monad

sumSquare(Option(3), Option(4))
// res7: Option[Int] = Some(value = 25)
sumSquare(List(1, 2, 3), List(4, 5))
// res8: List[Int] = List(17, 26, 20, 29, 25, 34)

```

We can rewrite this code using for comprehensions. The compiler will "do the right thing" by rewriting our comprehension in terms of `flatMap` and `map` and inserting the correct implicit conversions to use our `Monad`:

```

def sumSquare[F[_]: Monad](a: F[Int], b: F[Int]): F[Int] =
  for {
    x <- a
    y <- b
  } yield x*x + y*y

sumSquare(Option(3), Option(4))

```

```
// res10: Option[Int] = Some(value = 25)
sumSquare(List(1, 2, 3), List(4, 5))
// res11: List[Int] = List(17, 26, 20, 29, 25, 34)
```

That's more or less everything we need to know about the generalities of monads in Cats. Now let's take a look at some useful monad instances that we haven't seen in the Scala standard library.

6.3 The Identity Monad

In the previous section we demonstrated Cats' `flatMap` and `map` syntax by writing a method that abstracted over different monads:

```
import cats.Monad
import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatMap

def sumSquare[F[_]: Monad](a: F[Int], b: F[Int]): F[Int] =
  for {
    x <- a
    y <- b
  } yield x*x + y*y
```

This method works well on `Options` and `Lists` but we can't call it passing in plain values:

```
sumSquare(3, 4)
// error:
// Found:    (3 : Int)
// Required: ([_ ] => Any)[Int]
// Note that implicit conversions were not tried because the result of
// an implicit conversion
// must be more specific than ([_ ] => Any)[Int]
// pure(123)
//      ^
// error:
// Found:    (4 : Int)
// Required: ([_ ] => Any)[Int]
```

```
// Note that implicit conversions were not tried because the result of
// an implicit conversion
// must be more specific than ([_ ] => Any)[Int]
// def map[A, B](initial: Id[A])(func: A => B): Id[B] =
//           ^
// error:
// No given instance of type cats.Monad[[_ ] => Any] was found for an
// implicit parameter of method sumSquare in object MdocApp
// def map[A, B](initial: Id[A])(func: A => B): Id[B] =
//
```

It would be incredibly useful if we could use `sumSquare` with parameters that were either in a monad or not in a monad at all. This would allow us to abstract over monadic and non-monadic code. Fortunately, Cats provides the `Id` type to bridge the gap:

```
import cats.Id

sumSquare(3 : Id[Int], 4 : Id[Int])
// res1: Int = 25
```

`Id` allows us to call our monadic method using plain values. However, the exact semantics are difficult to understand. We cast the parameters to `sumSquare` as `Id[Int]` and received an `Id[Int]` back as a result!

What's going on? Here is the definition of `Id` to explain:

```
package cats

type Id[A] = A
```

`Id` is actually a type alias that turns an atomic type into a single-parameter type constructor. We can cast any value of any type to a corresponding `Id`:

```
"Dave" : Id[String]
// res2: String = "Dave"
123 : Id[Int]
// res3: Int = 123
List(1, 2, 3) : Id[List[Int]]
```

```
// res4: List[Int] = List(1, 2, 3)
```

Cats provides instances of various type classes for `Id`, including `Functor` and `Monad`. These let us call `map`, `flatMap`, and `pure` passing in plain values:

```
val a = Monad[Id].pure(3)
// a: Int = 3
val b = Monad[Id].flatMap(a)(_ + 1)
// b: Int = 4

import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatMap

for {
  x <- a
  y <- b
} yield x + y
// res5: Int = 7
```

The ability to abstract over monadic and non-monadic code is extremely powerful. For example, we can run code asynchronously in production using `Future` and synchronously in test using `Id`. We'll see this in our first case study in Chapter 10.

6.3.1 Exercise: Monadic Secret Identities

Implement `pure`, `map`, and `flatMap` for `Id`! What interesting discoveries do you uncover about the implementation?

See the solution

6.4 Either

Let's look at another useful monad: the `Either` type from the Scala standard library. In Scala 2.11 and earlier, many people didn't consider `Either` a monad because it didn't have `map` and `flatMap` methods. In Scala 2.12, however, `Either` became *right biased*.

6.4.1 Left and Right Bias

In Scala 2.11, Either had no default map or flatMap method. This made the Scala 2.11 version of Either inconvenient to use in for comprehensions. We had to insert calls to .right in every generator clause:

```
val either1: Either[String, Int] = Right(10)
val either2: Either[String, Int] = Right(32)

for {
  a <- either1.right
  b <- either2.right
} yield a + b
```

In Scala 2.12, Either was redesigned. The modern Either makes the decision that the right side represents the success case and thus supports map and flatMap directly. This makes for comprehensions much more pleasant:

```
for {
  a <- either1
  b <- either2
} yield a + b
// res1: Either[String, Int] = Right(value = 42)
```

Cats back-ports this behaviour to Scala 2.11 via the cats.syntax.either import, allowing us to use right-biased Either in all supported versions of Scala. In Scala 2.12+ we can either omit this import or leave it in place without breaking anything:

```
import cats.syntax.either._ // for map and flatMap

for {
  a <- either1
  b <- either2
} yield a + b
```

6.4.2 Creating Instances

In addition to creating instances of `Left` and `Right` directly, we can also import the `asLeft` and `asRight` extension methods from `cats.syntax.either`:

```
import cats.syntax.either._ // for asRight

val a = 3.asRight[String]
// a: Either[String, Int] = Right(value = 3)
val b = 4.asRight[String]
// b: Either[String, Int] = Right(value = 4)

for {
  x <- a
  y <- b
} yield x*x + y*y
// res3: Either[String, Int] = Right(value = 25)
```

These “smart constructors” have advantages over `Left.apply` and `Right.apply` because they return results of type `Either` instead of `Left` and `Right`. This helps avoid type inference problems caused by over-narrowing, like the issue in the example below:

```
def countPositive(nums: List[Int]) =
  nums.foldLeft(Right(0)) { (accumulator, num) =>
    if(num > 0) {
      accumulator.map(_ + 1)
    } else {
      Left("Negative. Stopping!")
    }
  }
// error:
// Found: Either[Nothing, Int]
// Required: Right[Nothing, Int]
//           accumulator.map(_ + 1)
//           ^^^^^^^^^^^^^^^^^^
// error:
// Found: Left[String, Any]
// Required: Right[Nothing, Int]
```

This code fails to compile for two reasons:

1. the compiler infers the type of the accumulator as Right instead of Either;
2. we didn't specify type parameters for Right.apply so the compiler infers the left parameter as Nothing.

Switching to asRight avoids both of these problems. asRight has a return type of Either, and allows us to completely specify the type with only one type parameter:

```
def countPositive(nums: List[Int]) =  
  nums.foldLeft(0.asRight[String]) { (accumulator, num) =>  
    if(num > 0) {  
      accumulator.map(_ + 1)  
    } else {  
      Left("Negative. Stopping!")  
    }  
  }  
  
countPositive(List(1, 2, 3))  
// res5: Either[String, Int] = Right(value = 3)  
countPositive(List(1, -2, 3))  
// res6: Either[String, Int] = Left(value = "Negative. Stopping!")
```

cats.syntax.either adds some useful extension methods to the Either companion object. The catchOnly and catchNonFatal methods are great for capturing Exceptions as instances of Either:

```
Either.catchOnly[NumberFormatException]("foo".toInt)  
// res7: Either[NumberFormatException, Int] = Left(  
//   value = java.lang.NumberFormatException: For input string: "foo"  
// )  
Either.catchNonFatal(sys.error("Badness"))  
// res8: Either[Throwable, Nothing] = Left(  
//   value = java.lang.RuntimeException: Badness  
// )
```

There are also methods for creating an Either from other data types:

```
Either.fromTry(scala.util.Try("foo".toInt))
// res9: Either[Throwable, Int] = Left(
//   value = java.lang.NumberFormatException: For input string: "foo"
// )
Either.fromOption[String, Int](None, "Badness")
// res10: Either[String, Int] = Left(value = "Badness")
```

6.4.3 Transforming Eithers

`cats.syntax.either` also adds some useful methods for instances of `Either`.

Users of Scala 2.11 or 2.12 can use `orElse` and `getOrElse` to extract values from the right side or return a default:

```
import cats.syntax.either._

"Error".asLeft[Int].getOrElse(0)
// res11: Int = 0
"Error".asLeft[Int].orElse(2.asRight[String])
// res12: Either[String, Int] = Right(value = 2)
```

The `ensure` method allows us to check whether the right-hand value satisfies a predicate:

```
-1.asRight[String].ensure("Must be non-negative!")(_ > 0)
// res13: Either[String, Int] = Left(value = "Must be non-negative!")
```

The `recover` and `recoverWith` methods provide similar error handling to their namesakes on `Future`:

```
"error".asLeft[Int].recover {
  case _: String => -1
}
// res14: Either[String, Int] = Right(value = -1)

"error".asLeft[Int].recoverWith {
  case _: String => Right(-1)
```

```

}
// res15: Either[String, Int] = Right(value = -1)

```

There are `leftMap` and `bimap` methods to complement `map`:

```

"foo".asLeft[Int].leftMap(_.reverse)
// res16: Either[String, Int] = Left(value = "oof")
6.asRight[String].bimap(_.reverse, _ * 7)
// res17: Either[String, Int] = Right(value = 42)
"bar".asLeft[Int].bimap(_.reverse, _ * 7)
// res18: Either[String, Int] = Left(value = "rab")

```

The `swap` method lets us exchange left for right:

```

123.asRight[String]
// res19: Either[String, Int] = Right(value = 123)
123.asRight[String].swap
// res20: Either[Int, String] = Left(value = 123)

```

Finally, Cats adds a host of conversion methods: `toOption`, `toList`, `toTry`, `toValidated`, and so on.

6.4.4 Error Handling

`Either` is typically used to implement fail-fast error handling. We sequence computations using `flatMap` as usual. If one computation fails, the remaining computations are not run:

```

for {
  a <- 1.asRight[String]
  b <- 0.asRight[String]
  c <- if(b == 0) "DIV0".asLeft[Int]
        else (a / b).asRight[String]
} yield c * 100
// res21: Either[String, Int] = Left(value = "DIV0")

```

When using `Either` for error handling, we need to determine what type we want to use to represent errors. We could use `Throwable` for this:

```
type Result[A] = Either[Throwable, A]
```

This gives us similar semantics to `scala.util.Try`. The problem, however, is that `Throwable` is an extremely broad type. We have (almost) no idea about what type of error occurred.

Another approach is to define an algebraic data type to represent errors that may occur in our program:

```
object wrapper {
    sealed trait LoginError extends Product with Serializable

    final case class UserNotFound(username: String)
        extends LoginError

    final case class PasswordIncorrect(username: String)
        extends LoginError

    case object UnexpectedError extends LoginError
}; import wrapper._

case class User(username: String, password: String)

type LoginResult = Either[LoginError, User]
```

This approach solves the problems we saw with `Throwable`. It gives us a fixed set of expected error types and a catch-all for anything else that we didn't expect. We also get the safety of exhaustivity checking on any pattern matching we do:

```
// Choose error-handling behaviour based on type:
def handleError(error: LoginError): Unit =
    error match {
        case UserNotFound(u) =>
            println(s"User not found: $u")

        case PasswordIncorrect(u) =>
            println(s"Password incorrect: $u")

        case UnexpectedError =>
```

```
    println(s"Unexpected error")
}

val result1: LoginResult = User("dave", "passw0rd").asRight
// result1: Either[LoginError, User] = Right(
//   value = User(username = "dave", password = "passw0rd")
// )
val result2: LoginResult = UserNotFound("dave").asLeft
// result2: Either[LoginError, User] = Left(
//   value = UserNotFound(username = "dave")
// )

result1.fold(handleError, println)
// User(dave,passw0rd)
result2.fold(handleError, println)
// User not found: dave
```

6.4.5 Exercise: What is Best?

Is the error handling strategy in the previous examples well suited for all purposes? What other features might we want from error handling?

See the solution

6.5 Aside: Error Handling and MonadError

Cats provides an additional type class called `MonadError` that abstracts over `Either`-like data types that are used for error handling. `MonadError` provides extra operations for raising and handling errors.

This Section is Optional!

You won't need to use `MonadError` unless you need to abstract over error handling monads. For example, you can use `MonadError` to abstract over `Future` and `Try`, or over `Either` and `EitherT` (which we will meet in Chapter 7).

If you don't need this kind of abstraction right now, feel free to skip

onwards to Section 6.6.

6.5.1 The MonadError Type Class

Here is a simplified version of the definition of `MonadError`:

```
package cats

trait MonadError[F[_], E] extends Monad[F] {
  // Lift an error into the `F` context:
  def raiseError[A](e: E): F[A]

  // Handle an error, potentially recovering from it:
  def handleErrorWith[A](fa: F[A])(f: E => F[A]): F[A]

  // Handle all errors, recovering from them:
  def handleError[A](fa: F[A])(f: E => A): F[A]

  // Test an instance of `F`,
  // failing if the predicate is not satisfied:
  def ensure[A](fa: F[A])(e: E)(f: A => Boolean): F[A]
}
```

`MonadError` is defined in terms of two type parameters:

- `F` is the type of the monad;
- `E` is the type of error contained within `F`.

To demonstrate how these parameters fit together, here's an example where we instantiate the type class for `Either`:

```
import cats.MonadError
import cats.instances.either._ // for MonadError

type ErrorOr[A] = Either[String, A]

val monadError = MonadError[ErrorOr, String]
```

ApplicativeError

In reality, `MonadError` extends another type class called `ApplicativeError`. However, we won't encounter `Applicatives` until Chapter 8. The semantics are the same for each type class so we can ignore this detail for now.

6.5.2 Raising and Handling Errors

The two most important methods of `MonadError` are `raiseError` and `handleErrorWith`. `raiseError` is like the `pure` method for `Monad` except that it creates an instance representing a failure:

```
val success = monadError.pure(42)
// success: Either[String, Int] = Right(value = 42)
val failure = monadError.raiseError("Badness")
// failure: Either[String, Nothing] = Left(value = "Badness")
```

`handleErrorWith` is the complement of `raiseError`. It allows us to consume an error and (possibly) turn it into a success, similar to the `recover` method of `Future`:

```
monadError.handleErrorWith(failure) {
  case "Badness" =>
    monadError.pure("It's ok")

  case _ =>
    monadError.raiseError("It's not ok")
}
// res0: Either[String, String] = Right(value = "It's ok")
```

If we know we can handle all possible errors we can use `handleWith`.

```
monadError.handleError(failure) {
  case "Badness" => 42

  case _ => -1
```

```

}
// res1: Either[String, Int] = Right(value = 42)

```

There is another useful method called `ensure` that implements filter-like behaviour. We test the value of a successful monad with a predicate and specify an error to raise if the predicate returns false:

```

monadError.ensure(success)("Number too low!")(_ > 1000)
// res2: Either[String, Int] = Left(value = "Number too low!")

```

Cats provides syntax for `raiseError` and `handleErrorWith` via `cats.syntax.applicativeError` and `ensure` via `cats.syntax.monadError`:

```

import cats.syntax.applicative._      // for pure
import cats.syntax.applicativeError._ // for raiseError etc
import cats.syntax.monadError._       // for ensure

val success = 42.pure[ErrorOr]
// success: Either[String, Int] = Right(value = 42)
val failure = "Badness".raiseError[ErrorOr, Int]
// failure: Either[String, Int] = Left(value = "Badness")
failure.handleErrorWith{
  case "Badness" =>
    256.pure

  case _ =>
    ("It's not ok").raiseError
}

// res4: Either[String, Int] = Right(value = 256)
success.ensure("Number to low!")(_ > 1000)
// res5: Either[String, Int] = Left(value = "Number to low!")

```

There are other useful variants of these methods. See the source of `cats.MonadError` and `cats.ApplicativeError` for more information.

6.5.3 Instances of MonadError

Cats provides instances of `MonadError` for numerous data types including `Either`, `Future`, and `Try`. The instance for `Either` is customisable to any error

type, whereas the instances for Future and Try always represent errors as Throwables:

```
import scala.util.Try
import cats.instances.try_._ // for MonadError

val exn: Throwable =
  new RuntimeException("It's all gone wrong")

exn.raiseError[Try, Int]
// res6: Try[Int] = Failure(
//   exception = java.lang.RuntimeException: It's all gone wrong
// )
```

6.5.4 Exercise: Abstracting

Implement a method validateAdult with the following signature

```
def validateAdult[F[_]](age: Int)(implicit me: MonadError[F, Throwable]): F[Int] =
  ???
```

When passed an age greater than or equal to 18 it should return that value as a success. Otherwise it should return a error represented as an IllegalArgumentException.

Here are some examples of use.

```
validateAdult[Try](18)
// res7: Try[Int] = Success(value = 18)
validateAdult[Try](8)
// res8: Try[Int] = Failure(
//   exception = java.lang.IllegalArgumentException: Age must be
//   greater than or equal to 18
// )
type ExceptionOr[A] = Either[Throwable, A]
validateAdult[ExceptionOr](-1)
// res9: Either[Throwable, Int] = Left(
//   value = java.lang.IllegalArgumentException: Age must be greater
```

```
    than or equal to 18  
// )
```

See the solution

6.6 The Eval Monad

`cats.Eval` is a monad that allows us to abstract over different *models of evaluation*. We typically talk of two such models: *eager* and *lazy*, also called *call-by-value* and *call-by-name* respectively. `Eval` also allows for a result to be *memoized*, which gives us *call-by-need* evaluation.

`Eval` is also *stack-safe*, which means we can use it in very deep recursions without blowing up the stack.

6.6.1 Eager, Lazy, Memoized, Oh My!

What do these terms for models of evaluation mean? Let's see some examples.

Let's first look at Scala `vals`. We can see the evaluation model using a computation with a visible side-effect. In the following example, the code to compute the value of `x` happens at place where it is defined rather than on access. Accessing `x` recalls the stored value without re-running the code.

```
val x = {  
  println("Computing X")  
  math.random()  
}  
// Computing X  
// x: Double = 0.4353344646800942  
  
x // first access  
// res0: Double = 0.4353344646800942 // first access  
x // second access  
// res1: Double = 0.4353344646800942
```

This is an example of call-by-value evaluation:

- the computation is evaluated at point where it is defined (eager); and
- the computation is evaluated once (memoized).

Let's look at an example using a `def`. The code to compute `y` below is not run until we use it, and is re-run on every access:

```
def y = {  
    println("Computing Y")  
    math.random()  
}  
  
y // first access  
// Computing Y  
// res2: Double = 0.15205353185949966 // first access  
y // second access  
// Computing Y  
// res3: Double = 0.7554070145386537
```

These are the properties of call-by-name evaluation:

- the computation is evaluated at the point of use (lazy); and
- the computation is evaluated each time it is used (not memoized).

Last but not least, `lazy vals` are an example of call-by-need evaluation. The code to compute `z` below is not run until we use it for the first time (lazy). The result is then cached and re-used on subsequent accesses (memoized):

```
lazy val z = {  
    println("Computing Z")  
    math.random()  
}  
  
z // first access  
// Computing Z  
// res4: Double = 0.8912832940383894 // first access  
z // second access  
// res5: Double = 0.8912832940383894
```

Let's summarize. There are two properties of interest:

- evaluation at the point of definition (eager) versus at the point of use (lazy); and
- values are saved once evaluated (memoized) or not (not memoized).

There are three possible combinations of these properties:

- call-by-value which is eager and memoized;
- call-by-name which is lazy and not memoized; and
- call-by-need which is lazy and memoized.

The final combination, eager and not memoized, is not possible.

6.6.2 Eval's Models of Evaluation

Eval has three subtypes: Now, Always, and Later. They correspond to call-by-value, call-by-name, and call-by-need respectively. We construct these with three constructor methods, which create instances of the three classes and return them typed as Eval:

```
import cats.Eval

val now = Eval.now(math.random() + 1000)
// now: Eval[Double] = Now(value = 1000.4543272915879)
val always = Eval.always(math.random() + 3000)
// always: Eval[Double] = cats.Always@455761d7
val later = Eval.later(math.random() + 2000)
// later: Eval[Double] = cats.Later@e4e1d80
```

We can extract the result of an Eval using its value method:

```
now.value
// res6: Double = 1000.4543272915879
always.value
// res7: Double = 3000.2884774338427
later.value
// res8: Double = 2000.2189275727587
```

Each type of `Eval` calculates its result using one of the evaluation models defined above. `Eval.now` captures a value *right now*. Its semantics are similar to a `val`—eager and memoized:

```
val x = Eval.now{
    println("Computing X")
    math.random()
}
// Computing X
// x: Eval[Double] = Now(value = 0.7799161124655586)

x.value // first access
// res10: Double = 0.7799161124655586 // first access
x.value // second access
// res11: Double = 0.7799161124655586
```

`Eval.always` captures a lazy computation, similar to a `def`:

```
val y = Eval.always{
    println("Computing Y")
    math.random()
}
// y: Eval[Double] = cats.Always@2e210528

y.value // first access
// Computing Y
// res12: Double = 0.18918489280963213 // first access
y.value // second access
// Computing Y
// res13: Double = 0.4502033222332241
```

Finally, `Eval.later` captures a lazy, memoized computation, similar to a `lazy val`:

```
val z = Eval.later{
    println("Computing Z")
    math.random()
}
// z: Eval[Double] = cats.Later@7b54580f
```

```

z.value // first access
// Computing Z
// res14: Double = 0.8083673491682185 // first access
z.value // second access
// res15: Double = 0.8083673491682185

```

The three behaviours are summarized below:

Scala	Cats	Properties
val	Now	eager, memoized
def	Always	lazy, not memoized
lazy val	Later	lazy, memoized

6.6.3 Eval as a Monad

Like all monads, `Eval`'s `map` and `flatMap` methods add computations to a chain. In this case, however, the chain is stored explicitly as a list of functions. The functions aren't run until we call `Eval`'s `value` method to request a result:

```

val greeting = Eval
  .always{ println("Step 1"); "Hello" }
  .map{ str => println("Step 2"); s"$str world" }
// greeting: Eval[String] = cats.Eval$anon$4@573d76b

greeting.value
// Step 1
// Step 2
// res16: String = "Hello world"

```

Note that, while the semantics of the originating `Eval` instances are maintained, mapping functions are always called lazily on demand (`def` semantics):

```

val ans = for {
  a <- Eval.now{ println("Calculating A"); 40 }
  b <- Eval.always{ println("Calculating B"); 2 }
} yield {
  println("Adding A and B")
}

```

```

    a + b
}
// Calculating A
// ans: Eval[Int] = cats.Eval$anon$4@7b2f6858

ans.value // first access
// Calculating B
// Adding A and B
// res17: Int = 42 // first access
ans.value // second access
// Calculating B
// Adding A and B
// res18: Int = 42

```

Eval has a `memoize` method that allows us to memoize a chain of computations. The result of the chain up to the call to `memoize` is cached, whereas calculations after the call retain their original semantics:

```

val saying = Eval
  .always{ println("Step 1"); "The cat" }
  .map{ str => println("Step 2"); s"$str sat on" }
  .memoize
  .map{ str => println("Step 3"); s"$str the mat" }
// saying: Eval[String] = cats.Eval$anon$4@5d813a50

saying.value // first access
// Step 1
// Step 2
// Step 3
// res19: String = "The cat sat on the mat" // first access
saying.value // second access
// Step 3
// res20: String = "The cat sat on the mat"

```

6.6.4 Trampolining and `Eval.defer`

One useful property of `Eval` is that its `map` and `flatMap` methods are *trampolined*. This means we can nest calls to `map` and `flatMap` arbitrarily without consuming stack frames. We call this property “*stack safety*”.

For example, consider this function for calculating factorials:

```
def factorial(n: BigInt): BigInt =  
  if(n == 1) n else n * factorial(n - 1)
```

It is relatively easy to make this method stack overflow:

```
factorial(50000)  
// java.lang.StackOverflowError  
// ...
```

We can rewrite the method using `Eval` to make it stack safe:

```
def factorial(n: BigInt): Eval[BigInt] =  
  if(n == 1) {  
    Eval.now(n)  
  } else {  
    factorial(n - 1).map(_ * n)  
  }  
  
factorial(50000).value  
// java.lang.StackOverflowError  
// ...
```

Oops! That didn't work—our stack still blew up! This is because we're still making all the recursive calls to `factorial` before we start working with `Eval`'s `map` method. We can work around this using `Eval.defer`, which takes an existing instance of `Eval` and defers its evaluation. The `defer` method is trampolined like `map` and `flatMap`, so we can use it as a quick way to make an existing operation stack safe:

```
def factorial(n: BigInt): Eval[BigInt] =  
  if(n == 1) {  
    Eval.now(n)  
  } else {  
    Eval.defer(factorial(n - 1).map(_ * n))  
  }  
  
factorial(50000).value  
// res: A very big value
```

Eval is a useful tool to enforce stack safety when working on very large computations and data structures. However, we must bear in mind that trampolining is not free. It avoids consuming stack by creating a chain of function objects on the heap. There are still limits on how deeply we can nest computations, but they are bounded by the size of the heap rather than the stack.

6.6.5 Exercise: Safer Folding using Eval

The naive implementation of foldRight below is not stack safe. Make it so using Eval:

```
def foldRight[A, B](as: List[A], acc: B)(fn: (A, B) => B): B =  
  as match {  
    case head :: tail =>  
      fn(head, foldRight(tail, acc)(fn))  
    case Nil =>  
      acc  
  }
```

See the solution

6.7 The Writer Monad

`cats.data.Writer` is a monad that lets us carry a log along with a computation. We can use it to record messages, errors, or additional data about a computation, and extract the log alongside the final result.

One common use for Writers is recording sequences of steps in multi-threaded computations where standard imperative logging techniques can result in interleaved messages from different contexts. With Writer the log for the computation is tied to the result, so we can run concurrent computations without mixing logs.

Cats Data Types

Writer is the first data type we've seen from the `cats.data` package. This package provides instances of various type classes that produce useful semantics. Other examples from `cats.data` include the monad transformers that we will see in the next chapter, and the `Validated` type we will encounter in Chapter 8.

6.7.1 Creating and Unpacking Writers

A `Writer[W, A]` carries two values: a *log* of type `W` and a *result* of type `A`. We can create a `Writer` from values of each type as follows:

```
import cats.data.Writer
import cats.instances.vector._ // for Monoid

Writer(Vector(
  "It was the best of times",
  "it was the worst of times"
), 1859)
// res0: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("It was the best of times", "it was the worst of
//   times"), 1859)
// )
```

Notice that the type reported on the console is actually `WriterT[Id, Vector[String], Int]` instead of `Writer[Vector[String], Int]` as we might expect. In the spirit of code reuse, Cats implements `Writer` in terms of another type, `WriterT`. `WriterT` is an example of a new concept called a *monad transformer*, which we will cover in the next chapter.

Let's try to ignore this detail for now. `Writer` is a type alias for `WriterT`, so we can read types like `WriterT[Id, W, A]` as `Writer[W, A]`:

```
type Writer[W, A] = WriterT[Id, W, A]
```

For convenience, Cats provides a way of creating `Writers` specifying only the log or the result. If we only have a result we can use the standard pure syntax.

To do this we must have a `Monoid[W]` in scope so Cats knows how to produce an empty log:

```
import cats.instances.vector._    // for Monoid
import cats.syntax.applicative._ // for pure

type Logged[A] = Writer[Vector[String], A]

123.pure[Logged]
// res1: WriterT[Id, Vector[String], Int] = WriterT(run = (Vector(),
  123))
```

If we have a log and no result we can create a `Writer[Unit]` using the `tell` syntax from `cats.syntax.writer`:

```
import cats.syntax.writer._ // for tell

Vector("msg1", "msg2", "msg3").tell
// res2: WriterT[Id, Vector[String], Unit] = WriterT(
//   run = (Vector("msg1", "msg2", "msg3"), ()))
// )
```

If we have both a result and a log, we can either use `Writer.apply` or we can use the `writer` syntax from `cats.syntax.writer`:

```
import cats.syntax.writer._ // for writer

val a = Writer(Vector("msg1", "msg2", "msg3"), 123)
// a: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("msg1", "msg2", "msg3"), 123)
// )
val b = 123.writer(Vector("msg1", "msg2", "msg3"))
// b: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("msg1", "msg2", "msg3"), 123)
// )
```

We can extract the result and log from a `Writer` using the `value` and `written` methods respectively:

```

val aResult: Int =
  a.value
// aResult: Int = 123
val aLog: Vector[String] =
  a.written
// aLog: Vector[String] = Vector("msg1", "msg2", "msg3")

```

We can extract both values at the same time using the `run` method:

```

val (log, result) = b.run
// log: Vector[String] = Vector("msg1", "msg2", "msg3")
// result: Int = 123

```

6.7.2 Composing and Transforming Writers

The log in a `Writer` is preserved when we `map` or `flatMap` over it. `flatMap` appends the logs from the source `Writer` and the result of the user's sequencing function. For this reason it's good practice to use a `log` type that has an efficient append and concatenate operations, such as a `Vector`:

```

val writer1 = for {
  a <- 10.pure[Logged]
  _ <- Vector("a", "b", "c").tell
  b <- 32.writer(Vector("x", "y", "z"))
} yield a + b
// writer1: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("a", "b", "c", "x", "y", "z"), 42)
// )

writer1.run
// res3: Tuple2[Vector[String], Int] = (
//   Vector("a", "b", "c", "x", "y", "z"),
//   42
// )

```

In addition to transforming the result with `map` and `flatMap`, we can transform the log in a `Writer` with the `mapWritten` method:

```
val writer2 = writer1.mapWritten(_.map(_.toUpperCase))
// writer2: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("A", "B", "C", "X", "Y", "Z"), 42)
// )

writer2.run
// res4: Tuple2[Vector[String], Int] = (
//   Vector("A", "B", "C", "X", "Y", "Z"),
//   42
// )
```

We can transform both log and result simultaneously using `bimap` or `mapBoth`. `bimap` takes two function parameters, one for the log and one for the result. `mapBoth` takes a single function that accepts two parameters:

```
val writer3 = writer1.bimap(
  log => log.map(_.toUpperCase),
  res => res * 100
)
// writer3: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("A", "B", "C", "X", "Y", "Z"), 4200)
// )

writer3.run
// res5: Tuple2[Vector[String], Int] = (
//   Vector("A", "B", "C", "X", "Y", "Z"),
//   4200
// )

val writer4 = writer1.mapBoth { (log, res) =>
  val log2 = log.map(_ + "!")
  val res2 = res * 1000
  (log2, res2)
}
// writer4: WriterT[Id, Vector[String], Int] = WriterT(
//   run = (Vector("a!", "b!", "c!", "x!", "y!", "z!"), 42000)
// )

writer4.run
// res6: Tuple2[Vector[String], Int] = (
//   Vector("a!", "b!", "c!", "x!", "y!", "z!"),
```

```
// 42000
// )
```

Finally, we can clear the log with the `reset` method and swap log and result with the `swap` method:

```
val writer5 = writer1.reset
// writer5: WriterT[Id, Vector[String], Int] = WriterT(run = (Vector(),
//   42))

writer5.run
// res7: Tuple2[Vector[String], Int] = (Vector(), 42)

val writer6 = writer1.swap
// writer6: WriterT[Id, Int, Vector[String]] = WriterT(
//   run = (42, Vector("a", "b", "c", "x", "y", "z"))
// )

writer6.run
// res8: Tuple2[Int, Vector[String]] = (
//   42,
//   Vector("a", "b", "c", "x", "y", "z")
// )
```

6.7.3 Exercise: Show Your Working

Writers are useful for logging operations in multi-threaded environments. Let's confirm this by computing (and logging) some factorials.

The `factorial` function below computes a factorial and prints out the intermediate steps as it runs. The `slowly` helper function ensures this takes a while to run, even on the very small examples below:

```
def slowly[A](body: => A) =
  try body finally Thread.sleep(100)

def factorial(n: Int): Int = {
  val ans = slowly(if(n == 0) 1 else n * factorial(n - 1))
  println(s"fact $n $ans")
```

```
    ans  
}
```

Here's the output—a sequence of monotonically increasing values:

```
factorial(5)  
// fact 0 1  
// fact 1 1  
// fact 2 2  
// fact 3 6  
// fact 4 24  
// fact 5 120  
// res9: Int = 120
```

If we start several factorials in parallel, the log messages can become interleaved on standard out. This makes it difficult to see which messages come from which computation:

```
import scala.concurrent._  
import scala.concurrent.ExecutionContext.Implicits._  
import scala.concurrent.duration._  
  
Await.result(Future.sequence(Vector(  
  Future(factorial(5)),  
  Future(factorial(5))  
)), 5.seconds)  
// fact 0 1  
// fact 0 1  
// fact 1 1  
// fact 1 1  
// fact 2 2  
// fact 2 2  
// fact 3 6  
// fact 3 6  
// fact 4 24  
// fact 4 24  
// fact 5 120  
// fact 5 120  
// res: scala.collection.immutable.Vector[Int] =  
//   Vector(120, 120)
```

Rewrite factorial so it captures the log messages in a Writer. Demonstrate that this allows us to reliably separate the logs for concurrent computations.

See the solution

6.8 The Reader Monad

`cats.data.Reader` is a monad that allows us to sequence operations that depend on some input. Instances of Reader wrap up functions of one argument, providing us with useful methods for composing them.

One common use for Readers is dependency injection. If we have a number of operations that all depend on some external configuration, we can chain them together using a Reader to produce one large operation that accepts the configuration as a parameter and runs our program in the order specified.

6.8.1 Creating and Unpacking Readers

We can create a `Reader[A, B]` from a function `A => B` using the `Reader.apply` constructor:

```
import cats.data.Reader

final case class Cat(name: String, favoriteFood: String)

val catName: Reader[Cat, String] =
  Reader(cat => cat.name)
// catName: Kleisli[Id, Cat, String] = Kleisli(
//   run = repl.MdocSession$MdocApp0$$Lambda$17806/0
//     x00007f2d469a3000@4385db00
// )
```

We can extract the function again using the Reader's `run` method and call it using `apply` as usual:

```
catName.run(Cat("Garfield", "lasagne"))
// res1: String = "Garfield"
```

So far so simple, but what advantage do Readers give us over the raw functions?

6.8.2 Composing Readers

The power of Readers comes from their `map` and `flatMap` methods, which represent different kinds of function composition. We typically create a set of Readers that accept the same type of configuration, combine them with `map` and `flatMap`, and then call `run` to inject the config at the end.

The `map` method simply extends the computation in the Reader by passing its result through a function:

```
val greetKitty: Reader[Cat, String] =
  catName.map(name => s"Hello ${name}")

greetKitty.run(Cat("Heathcliff", "junk food"))
// res2: String = "Hello Heathcliff"
```

The `flatMap` method is more interesting. It allows us to combine readers that depend on the same input type. To illustrate this, let's extend our greeting example to also feed the cat:

```
val feedKitty: Reader[Cat, String] =
  Reader(cat => s"Have a nice bowl of ${cat.favoriteFood}")

val greetAndFeed: Reader[Cat, String] =
  for {
    greet <- greetKitty
    feed   <- feedKitty
  } yield s"$greet. $feed."

greetAndFeed(Cat("Garfield", "lasagne"))
// res3: String = "Hello Garfield. Have a nice bowl of lasagne."
greetAndFeed(Cat("Heathcliff", "junk food"))
```

```
// res4: String = "Hello Heathcliff. Have a nice bowl of junk food."
```

6.8.3 Exercise: Hacking on Readers

The classic use of Readers is to build programs that accept a configuration as a parameter. Let's ground this with a complete example of a simple login system. Our configuration will consist of two databases: a list of valid users and a list of their passwords:

```
final case class Db(  
    usernames: Map[Int, String],  
    passwords: Map[String, String]  
)
```

Start by creating a type alias `DbReader` for a Reader that consumes a `Db` as input. This will make the rest of our code shorter.

See the solution

Now create methods that generate `DbReaders` to look up the username for an `Int` user ID, and look up the password for a `String` username. The type signatures should be as follows:

```
def findUsername(userId: Int): DbReader[Option[String]] =  
    ???  
  
def checkPassword(  
    username: String,  
    password: String): DbReader[Boolean] =  
    ???
```

See the solution

Finally create a `checkLogin` method to check the password for a given user ID. The type signature should be as follows:

```
def checkLogin(  
    userId: Int,  
    password: String): DbReader[Boolean] =  
    ???
```

See the solution

You should be able to use `checkLogin` as follows:

```
val users = Map(  
    1 -> "dade",  
    2 -> "kate",  
    3 -> "margo"  
)  
  
val passwords = Map(  
    "dade" -> "zerocool",  
    "kate" -> "acidburn",  
    "margo" -> "secret"  
)  
  
val db = Db(users, passwords)  
  
checkLogin(1, "zerocool").run(db)  
// res7: Boolean = true  
checkLogin(4, "davinci").run(db)  
// res8: Boolean = false
```

6.8.4 When to Use Readers?

Readers provide a tool for doing dependency injection. We write steps of our program as instances of `Reader`, chain them together with `map` and `flatMap`, and build a function that accepts the dependency as input.

There are many ways of implementing dependency injection in Scala, from simple techniques like methods with multiple parameter lists, through implicit parameters and type classes, to complex techniques like the cake pattern and DI frameworks.

Readers are most useful in situations where:

- we are constructing a program that can easily be represented by a function;
- we need to defer injection of a known parameter or set of parameters;
- we want to be able to test parts of the program in isolation.

By representing the steps of our program as Readers we can test them as easily as pure functions, plus we gain access to the `map` and `flatMap` combinators.

For more complicated problems where we have lots of dependencies, or where a program isn't easily represented as a pure function, other dependency injection techniques tend to be more appropriate.

Kleisli Arrows

You may have noticed from console output that Reader is implemented in terms of another type called Kleisli. *Kleisli arrows* provide a more general form of Reader that generalise over the type constructor of the result type. We will encounter Kleislis again in Chapter 7.

6.9 The State Monad

`cats.data.State` allows us to pass additional state around as part of a computation. We define State instances representing atomic state operations and thread them together using `map` and `flatMap`. In this way we can model mutable state in a purely functional way, without using actual mutation.

6.9.1 Creating and Unpacking State

Boiled down to their simplest form, instances of `State[S, A]` represent functions of type `S => (S, A)`. `S` is the type of the state and `A` is the type of the result.

```
import cats.data.State

val a = State[Int, String]{ state =>
  (state, s"The state is $state")
}
```

In other words, an instance of `State` is a function that does two things:

- transforms an input state to an output state;
- computes a result.

We can “run” our monad by supplying an initial state. `State` provides three methods—`run`, `runS`, and `runA`—that return different combinations of state and result. Each method returns an instance of `Eval`, which `State` uses to maintain stack safety. We call the `value` method as usual to extract the actual result:

```
// Get the state and the result:
val (state, result) = a.run(10).value
// state: Int = 10
// result: String = "The state is 10"

// Get the state, ignore the result:
val justTheState = a.runS(10).value
// justTheState: Int = 10

// Get the result, ignore the state:
val justTheResult = a.runA(10).value
// justTheResult: String = "The state is 10"
```

6.9.2 Composing and Transforming State

As we’ve seen with `Reader` and `Writer`, the power of the `State` monad comes from combining instances. The `map` and `flatMap` methods thread the state from one instance to another. Each individual instance represents an atomic state transformation, and their combination represents a complete sequence of changes:

```

val step1 = State[Int, String]{ num =>
    val ans = num + 1
    (ans, s"Result of step1: $ans")
}

val step2 = State[Int, String]{ num =>
    val ans = num * 2
    (ans, s"Result of step2: $ans")
}

val both = for {
    a <- step1
    b <- step2
} yield (a, b)

val (state, result) = both.run(20).value
// state: Int = 42
// result: Tuple2[String, String] = (
//   "Result of step1: 21",
//   "Result of step2: 42"
// )

```

As you can see, in this example the final state is the result of applying both transformations in sequence. State is threaded from step to step even though we don't interact with it in the for comprehension.

The general model for using the State monad is to represent each step of a computation as an instance and compose the steps using the standard monad operators. Cats provides several convenience constructors for creating primitive steps:

- `get` extracts the state as the result;
- `set` updates the state and returns unit as the result;
- `pure` ignores the state and returns a supplied result;
- `inspect` extracts the state via a transformation function;
- `modify` updates the state using an update function.

```

val getDemo = State.get[Int]
// getDemo: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int, Int,
//     Int] = cats.data.IndexedStateT@2222b488
getDemo.run(10).value
// res1: Tuple2[Int, Int] = (10, 10)

val setDemo = State.set[Int](30)
// setDemo: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int, Int,
//     Unit] = cats.data.IndexedStateT@5bb84211
setDemo.run(10).value
// res2: Tuple2[Int, Unit] = (30, ())

val pureDemo = State.pure[Int, String]("Result")
// pureDemo: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int, Int,
//     String] = cats.data.IndexedStateT@540ad1b4
pureDemo.run(10).value
// res3: Tuple2[Int, String] = (10, "Result")

val inspectDemo = State.inspect[Int, String](x => s"${x}!")
// inspectDemo: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int,
//     Int, String] = cats.data.IndexedStateT@72a39528
inspectDemo.run(10).value
// res4: Tuple2[Int, String] = (10, "10!")

val modifyDemo = State.modify[Int](_ + 1)
// modifyDemo: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int,
//     Int, Unit] = cats.data.IndexedStateT@4512f900
modifyDemo.run(10).value
// res5: Tuple2[Int, Unit] = (11, ())

```

We can assemble these building blocks using a for comprehension. We typically ignore the result of intermediate stages that only represent transformations on the state:

```

import cats.data.State
import State._

val program: State[Int, (Int, Int, Int)] = for {
  a <- get[Int]
  _ <- set[Int](a + 1)
  b <- get[Int]
  _ <- modify[Int](_ + 1)
}

```

```

c <- inspect[Int, Int](_ * 1000)
} yield (a, b, c)
// program: IndexedStateT[[A >: Nothing <: Any] => Eval[A], Int, Int,
// Tuple3[Int, Int, Int]] = cats.data.IndexedStateT@5c238379

val (state, result) = program.run(1).value
// state: Int = 3
// result: Tuple3[Int, Int, Int] = (1, 2, 3000)

```

6.9.3 Exercise: Post-Order Calculator

The State monad allows us to implement simple interpreters for complex expressions, passing the values of mutable registers along with the result. We can see a simple example of this by implementing a calculator for post-order integer arithmetic expressions.

In case you haven't heard of post-order expressions before (don't worry if you haven't), they are a mathematical notation where we write the operator *after* its operands. So, for example, instead of writing $1 + 2$ we would write:

```
1 2 +
```

Although post-order expressions are difficult for humans to read, they are easy to evaluate in code. All we need to do is traverse the symbols from left to right, carrying a *stack* of operands with us as we go:

- when we see a number, we push it onto the stack;
- when we see an operator, we pop two operands off the stack, operate on them, and push the result in their place.

This allows us to evaluate complex expressions without using parentheses. For example, we can evaluate $(1 + 2) * 3$ as follows:

```

1 2 + 3 * // see 1, push onto stack
2 + 3 * // see 2, push onto stack
+ 3 *    // see +, pop 1 and 2 off of stack,
          //           push (1 + 2) = 3 in their place

```

```
3 3 *      // see 3, push onto stack
3 *       // see 3, push onto stack
*        // see *, pop 3 and 3 off of stack,
          //      push (3 * 3) = 9 in their place
```

Let's write an interpreter for these expressions. We can parse each symbol into a State instance representing a transformation on the stack and an intermediate result. The state instances can be threaded together using flatMap to produce an interpreter for any sequence of symbols.

Start by writing a function evalOne that parses a single symbol into an instance of State. Use the code below as a template. Don't worry about error handling for now—if the stack is in the wrong configuration, it's OK to throw an exception.

```
import cats.data.State

type CalcState[A] = State[List[Int], A]

def evalOne(sym: String): CalcState[Int] = ???
```

If this seems difficult, think about the basic form of the State instances you're returning. Each instance represents a functional transformation from a stack to a pair of a stack and a result. You can ignore any wider context and focus on just that one step:

```
State[List[Int], Int] { oldStack =>
  val newStack = someTransformation(oldStack)
  val result   = someCalculation
  (newStack, result)
}
```

Feel free to write your Stack instances in this form or as sequences of the convenience constructors we saw above.

See the solution

evalOne allows us to evaluate single-symbol expressions as follows. We call runA supplying Nil as an initial stack, and call value to unpack the resulting Eval instance:

```
evalOne("42").runA(Nil).value
// res10: Int = 42
```

We can represent more complex programs using `evalOne`, `map`, and `flatMap`. Note that most of the work is happening on the stack, so we ignore the results of the intermediate steps for `evalOne("1")` and `evalOne("2")`:

```
val program = for {
  _ <- evalOne("1")
  _ <- evalOne("2")
  ans <- evalOne("+")
} yield ans
// program: IndexedStateT[[A >: Nothing <: Any] => Eval[A], List[Int],
// List[Int], Int] = cats.data.IndexedStateT@5e267e38

program.runA(Nil).value
// res11: Int = 3
```

Generalise this example by writing an `evalAll` method that computes the result of a `List[String]`. Use `evalOne` to process each symbol, and thread the resulting State monads together using `flatMap`. Your function should have the following signature:

```
def evalAll(input: List[String]): CalcState[Int] =
  ???
```

See the solution

We can use `evalAll` to conveniently evaluate multi-stage expressions:

```
val multistageProgram = evalAll(List("1", "2", "+", "3", "*"))
// multistageProgram: IndexedStateT[[A >: Nothing <: Any] => Eval[A],
// List[Int], List[Int], Int] = cats.data.IndexedStateT@30c2ba01

multistageProgram.runA(Nil).value
// res13: Int = 9
```

Because `evalOne` and `evalAll` both return instances of `State`, we can thread these results together using `flatMap`. `evalOne` produces a simple stack

transformation and evalAll produces a complex one, but they're both pure functions and we can use them in any order as many times as we like:

```
val biggerProgram = for {
    -> evalAll(List("1", "2", "+"))
    -> evalAll(List("3", "4", "+"))
    ans <- evalOne("*")
} yield ans
// biggerProgram: IndexedStateT[[A >: Nothing <: Any] => Eval[A], List[Int], List[Int], Int] = cats.data.IndexedStateT@624a9fe0

biggerProgram.runA(Nil).value
// res14: Int = 21
```

Complete the exercise by implementing an evalInput function that splits an input string into symbols, calls evalAll, and runs the result with an initial stack.

See the solution

6.10 Defining Custom Monads

We can define a `Monad` for a custom type by providing implementations of three methods: `flatMap`, `pure`, and a method we haven't seen yet called `tailRecM`. Here is an implementation of `Monad` for `Option` as an example:

```
import cats.Monad
import scala.annotation.tailrec

val optionMonad = new Monad[Option] {
    def flatMap[A, B](opt: Option[A])
        (fn: A => Option[B]): Option[B] =
        opt.flatMap(fn)

    def pure[A](opt: A): Option[A] =
        Some(opt)

    @tailrec
    def tailRecM[A, B](a: A)(fn: A => Option[Either[A, B]]): Option[B] =
        {
```

```

fn(a) match {
  case None          => None
  case Some(Left(a1)) => tailRecM(a1)(fn)
  case Some(Right(b)) => Some(b)
}
}
}
}

```

The `tailRecM` method is an optimisation used in Cats to limit the amount of stack space consumed by nested calls to `flatMap`. The technique comes from a [2015 paper](#) by PureScript creator Phil Freeman. The method should recursively call itself until the result of `fn` returns a `Right`.

To motivate its use let's use the following example: Suppose we want to write a method that calls a function until the function indicates it should stop. The function will return a monad instance because, as we know, monads represent sequencing and many monads have some notion of stopping.

We can write this method in terms of `flatMap`.

```

import cats.syntax.flatMap._ // For flatMap

def retry[F[_]: Monad, A](start: A)(f: A => F[A]): F[A] =
  f(start).flatMap{ a =>
    retry(a)(f)
  }
}

```

Unfortunately it is not stack-safe. It works for small input.

```

import cats.instances.option._

retry(100)(a => if(a == 0) None else Some(a - 1))
// res1: Option[Int] = None

```

but if we try large input we get a `StackOverflowError`.

```

retry(100000)(a => if(a == 0) None else Some(a - 1))
// KABLOOIE!!!!

```

We can instead rewrite this method using `tailRecM`.

```
import cats.syntax.functor._ // for map

def retryTailRecM[F[_]: Monad, A](start: A)(f: A => F[A]): F[A] =
  Monad[F].tailRecM(start){ a =>
    f(a).map(a2 => Left(a2))
  }
```

Now it runs successfully no matter how many time we recurse.

```
retryTailRecM(100000)(a => if(a == 0) None else Some(a - 1))
// res2: Option[Int] = None
```

It's important to note that we have to explicitly call `tailRecM`. There isn't a code transformation that will convert non-tail recursive code into tail recursive code that uses `tailRecM`. However there are several utilities provided by the `Monad` type class that makes these kinds of methods easier to write. For example, we can rewrite `retry` in terms of `iterateWhileM` and we don't have to explicitly call `tailRecM`.

```
import cats.syntax.monad._ // for iterateWhileM

def retryM[F[_]: Monad, A](start: A)(f: A => F[A]): F[A] =
  start.iterateWhileM(f)(a => true)

retryM(100000)(a => if(a == 0) None else Some(a - 1))
// res3: Option[Int] = None
```

We'll see more methods that use `tailRecM` in Section 9.1.

All of the built-in monads in Cats have tail-recursive implementations of `tailRecM`, although writing one for custom monads can be a challenge... as we shall see.

6.10.1 Exercise: Branching out Further with Monads

Let's write a `Monad` for our `Tree` data type from last chapter. Here's the type again:

```
sealed trait Tree[+A]

final case class Branch[A](left: Tree[A], right: Tree[A])
  extends Tree[A]

final case class Leaf[A](value: A) extends Tree[A]

def branch[A](left: Tree[A], right: Tree[A]): Tree[A] =
  Branch(left, right)

def leaf[A](value: A): Tree[A] =
  Leaf(value)
```

Verify that the code works on instances of `Branch` and `Leaf`, and that the `Monad` provides Functor-like behaviour for free.

Also verify that having a `Monad` in scope allows us to use for comprehensions, despite the fact that we haven't directly implemented `flatMap` or `map` on `Tree`.

Don't feel you have to make `tailRecM` tail-recursive. Doing so is quite difficult. We've included both tail-recursive and non-tail-recursive implementations in the solutions so you can check your work.

See the solution

6.11 Summary

In this chapter we've seen monads up-close. We saw that `flatMap` can be viewed as an operator for sequencing computations, dictating the order in which operations must happen. From this viewpoint, `Option` represents a computation that can fail without an error message, `Either` represents computations that can fail with a message, `List` represents multiple possible results, and `Future` represents a computation that may produce a value at some point in the future.

We've also seen some of the custom types and data structures that Cats provides, including `Id`, `Reader`, `Writer`, and `State`. These cover a wide range of use cases.

Finally, in the unlikely event that we have to implement a custom monad, we've learned about defining our own instance using `tailRecM`. `tailRecM` is an odd wrinkle that is a concession to building a functional programming library that is stack-safe by default. We don't need to understand `tailRecM` to understand monads, but having it around gives us benefits of which we can be grateful when writing monadic code.

Chapter 7

Monad Transformers

Monads are [like burritos](#), which means that once you acquire a taste, you'll find yourself returning to them again and again. This is not without issues. As burritos can bloat the waist, monads can bloat the code base through nested for-comprehensions.

Imagine we are interacting with a database. We want to look up a user record. The user may or may not be present, so we return an `Option[User]`. Our communication with the database could fail for many reasons (network issues, authentication problems, and so on), so this result is wrapped up in an `Either`, giving us a final result of `Either[Error, Option[User]]`.

To use this value we must nest `flatMap` calls (or equivalently, for-comprehensions):

```
def lookupUserName(id: Long): Either[Error, Option[String]] =  
  for {  
    optUser <- lookupUser(id)  
  } yield {  
    for { user <- optUser } yield user.name  
  }
```

This quickly becomes very tedious.

7.1 Exercise: Composing Monads

A question arises. Given two arbitrary monads, can we combine them in some way to make a single monad? That is, do monads *compose*? We can try to write the code but we soon hit problems:

```
import cats.syntax.applicative._ // for pure

// Hypothetical example. This won't actually compile:
def compose[M1[_]: Monad, M2[_]: Monad] = {
    type Composed[A] = M1[M2[A]]

    new Monad[Composed] {
        def pure[A](a: A): Composed[A] =
            a.pure[M2].pure[M1]

        def flatMap[A, B](fa: Composed[A])
            (f: A => Composed[B]): Composed[B] =
            // Problem! How do we write flatMap?
            ???
    }
}
```

It is impossible to write a general definition of `flatMap` without knowing something about `M1` or `M2`. However, if we *do* know something about one or other monad, we can typically complete this code. For example, if we fix `M2` above to be `Option`, a definition of `flatMap` comes to light:

```
def flatMap[A, B](fa: Composed[A])
    (f: A => Composed[B]): Composed[B] =
    fa.flatMap(_.fold[Composed[B]](None.pure[M1])(f))
```

Notice that the definition above makes use of `None`—an `Option`-specific concept that doesn't appear in the general `Monad` interface. We need this extra detail to combine `Option` with other monads. Similarly, there are things about other monads that help us write composed `flatMap` methods for them. This is the idea behind monad transformers: Cats defines transformers for a variety of monads, each providing the extra knowledge we need to compose that monad with others. Let's look at some examples.

7.2 A Transformative Example

Cats provides transformers for many monads, each named with a T suffix: EitherT composes Either with other monads, OptionT composes Option, and so on.

Here's an example that uses OptionT to compose List and Option. We can use OptionT[List, A], aliased to ListOption[A] for convenience, to transform a List[Option[A]] into a single monad:

```
import cats.data.OptionT

type ListOption[A] = OptionT[List, A]
```

Note how we build ListOption from the inside out: we pass List, the type of the outer monad, as a parameter to OptionT, the transformer for the inner monad.

We can create instances of ListOption using the OptionT constructor, or more conveniently using pure:

```
import cats.instances.list._      // for Monad
import cats.syntax.applicative._ // for pure

val result1: ListOption[Int] = OptionT(List(Option(10)))
// result1: OptionT[List, Int] = OptionT(value = List(Some(value = 10)
    ))

val result2: ListOption[Int] = 32.pure[ListOption]
// result2: OptionT[List, Int] = OptionT(value = List(Some(value = 32)
    ))
```

The map and flatMap methods combine the corresponding methods of List and Option into single operations:

```
result1.flatMap { (x: Int) =>
  result2.map { (y: Int) =>
    x + y
  }
}
```

```
}
```

```
// res1: OptionT[List, Int] = OptionT(value = List(Some(value = 42)))
```

This is the basis of all monad transformers. The combined `map` and `flatMap` methods allow us to use both component monads without having to recursively unpack and repack values at each stage in the computation. Now let's look at the API in more depth.

Complexity of Imports

The imports in the code samples above hint at how everything bolts together.

We import `cats.syntax.applicative` to get the pure syntax. `pure` requires an implicit parameter of type `Applicative[ListOption]`. We haven't met Applicatives yet, but all Monads are also Applicatives so we can ignore that difference for now.

In order to generate our `Applicative[ListOption]` we need instances of `Applicative` for `List` and `OptionT`. `OptionT` is a Cats data type so its instance is provided by its companion object. The instance for `List` comes from `cats.instances.list`.

Notice we're not importing `cats.syntax.functor` or `cats.syntax.flatMap`. This is because `OptionT` is a concrete data type with its own explicit `map` and `flatMap` methods. It wouldn't cause problems if we imported the syntax—the compiler would ignore it in favour of the explicit methods.

Remember that we're subjecting ourselves to these shenanigans because we're stubbornly refusing to use the universal Cats import, `cats.implicits`. If we did use that import, all of the instances and syntax we needed would be in scope and everything would just work.

7.3 Monad Transformers in Cats

Each monad transformer is a data type, defined in `cats.data`, that allows us to *wrap* stacks of monads to produce new monads. We use the monads

we've built via the `Monad` type class. The main concepts we have to cover to understand monad transformers are:

- the available transformer classes;
- how to build stacks of monads using transformers;
- how to construct instances of a monad stack; and
- how to pull apart a stack to access the wrapped monads.

7.3.1 The Monad Transformer Classes

By convention, in Cats a monad `Foo` will have a transformer class called `FooT`. In fact, many monads in Cats are defined by combining a monad transformer with the `Id` monad. Concretely, some of the available instances are:

- `cats.data.OptionT` for `Option`;
- `cats.data.EitherT` for `Either`;
- `cats.data.ReaderT` for `Reader`;
- `cats.data.WriterT` for `Writer`;
- `cats.data.StateT` for `State`;
- `cats.data.IdT` for the `Id` monad.

Kleisli Arrows

In Section 6.8 we mentioned that the `Reader` monad was a specialisation of a more general concept called a “kleisli arrow”, represented in Cats as `cats.data.Kleisli`.

We can now reveal that `Kleisli` and `ReaderT` are, in fact, the same thing! `ReaderT` is actually a type alias for `Kleisli`. Hence, we were creating Readers last chapter and seeing `Kleislis` on the console.

7.3.2 Building Monad Stacks

All of these monad transformers follow the same convention. The transformer itself represents the *inner* monad in a stack, while the first type parameter

specifies the outer monad. The remaining type parameters are the types we've used to form the corresponding monads.

For example, our `ListOption` type above is an alias for `OptionT[List, A]` but the result is effectively a `List[Option[A]]`. In other words, we build monad stacks from the inside out:

```
type ListOption[A] = OptionT[List, A]
```

Many monads and all transformers have at least two type parameters, so we often have to define type aliases for intermediate stages.

For example, suppose we want to wrap `Either` around `Option`. `Option` is the innermost type so we want to use the `OptionT` monad transformer. We need to use `Either` as the first type parameter. However, `Either` itself has two type parameters and monads only have one. We need a type alias to convert the type constructor to the correct shape:

```
// Alias Either to a type constructor with one parameter:
type ErrorOr[A] = Either[String, A]

// Build our final monad stack using OptionT:
type ErrorOrOption[A] = OptionT[ErrorOr, A]
```

`ErrorOrOption` is a monad, just like `ListOption`. We can use `pure`, `map`, and `flatMap` as usual to create and transform instances:

```
import cats.instances.either._ // for Monad

val a = 10.pure[ErrorOrOption]
// a: OptionT[ErrorOr, Int] = OptionT(value = Right(value = Some(value
// = 10)))

val b = 32.pure[ErrorOrOption]
// b: OptionT[ErrorOr, Int] = OptionT(value = Right(value = Some(value
// = 32)))

val c = a.flatMap(x => b.map(y => x + y))
// c: OptionT[ErrorOr, Int] = OptionT(value = Right(value = Some(value
// = 42)))
```

Things become even more confusing when we want to stack three or more monads.

For example, let's create a Future of an Either of Option. Once again we build this from the inside out with an OptionT of an EitherT of Future. However, we can't define this in one line because EitherT has three type parameters:

```
case class EitherT[F[_], E, A](stack: F[Either[E, A]]) {  
    // etc...  
}
```

The three type parameters are as follows:

- F[_] is the outer monad in the stack (Either is the inner);
- E is the error type for the Either;
- A is the result type for the Either.

This time we create an alias for EitherT that fixes Future and Error and allows A to vary:

```
import scala.concurrent.Future  
import cats.data.{EitherT, OptionT}  
  
type FutureEither[A] = EitherT[Future, String, A]  
  
type FutureEitherOption[A] = OptionT[FutureEither, A]
```

Our mammoth stack now composes three monads and our map and flatMap methods cut through three layers of abstraction:

```
import cats.instances.future._ // for Monad  
import scala.concurrent.Await  
import scala.concurrent.ExecutionContext.Implicits.global  
import scala.concurrent.duration._  
  
val futureEitherOr: FutureEitherOption[Int] =  
    for {  
        a <- 10.pure[FutureEitherOption]  
        b <- 32.pure[FutureEitherOption]
```

```
    } yield a + b
```

Kind Projector

If you frequently find yourself defining multiple type aliases when building monad stacks, you may want to try the [Kind Projector](#) compiler plugin. Kind Projector enhances Scala's type syntax to make it easier to define partially applied type constructors. For example:

```
import cats.instances.option._ // for Monad // for Monad

123.pure[EitherT[Option, String, _]]
// res3: EitherT[[A >: Nothing <: Any] => Option[A], String, Int
//   ] = EitherT(
//     value = Some(value = Right(value = 123))
//   )
```

Kind Projector can't simplify all type declarations down to a single line, but it can reduce the number of intermediate type definitions needed to keep our code readable.

7.3.3 Constructing and Unpacking Instances

As we saw above, we can create transformed monad stacks using the relevant monad transformer's `apply` method or the usual `pure` syntax¹:

```
// Create using apply:
val errorStack1 = OptionT[ErrorOr, Int](Right(Some(10)))
// errorStack1: OptionT[ErrorOr, Int] = OptionT(
//   value = Right(value = Some(value = 10))
// )

// Create using pure:
val errorStack2 = 32.pure[ErrorOrOption]
```

¹Cats provides an instance of `MonadError` for `EitherT`, allowing us to create instances using `raiseError` as well as `pure`.

```
// errorStack2: OptionT[ErrorOr, Int] = OptionT(  
//   value = Right(value = Some(value = 32))  
// )
```

Once we've finished with a monad transformer stack, we can unpack it using its `value` method. This returns the untransformed stack. We can then manipulate the individual monads in the usual way:

```
// Extracting the untransformed monad stack:  
errorStack1.value  
// res4: Either[String, Option[Int]] = Right(value = Some(value = 10))  
  
// Mapping over the Either in the stack:  
errorStack2.value.map(_.getOrElse(-1))  
// res5: Either[String, Int] = Right(value = 32)
```

Each call to `value` unpacks a single monad transformer. We may need more than one call to completely unpack a large stack. For example, to `Await` the `FutureEitherOption` stack above, we need to call `value` twice:

```
futureEitherOr  
// res6: OptionT[FutureEither, Int] = OptionT(  
//   value = EitherT(value = Future(Success(Right(Some(42)))))  
// )  
  
val intermediate = futureEitherOr.value  
// intermediate: EitherT[[T >: Nothing <: Any] => Future[T], String,  
//   Option[Int]] = EitherT(  
//   value = Future(Success(Right(Some(42))))  
// )  
  
val stack = intermediate.value  
// stack: Future[Either[String, Option[Int]]] = Future(Success(Right(  
//   Some(42))))  
  
Await.result(stack, 1.second)  
// res7: Either[String, Option[Int]] = Right(value = Some(value = 42))
```

7.3.4 Default Instances

Many monads in Cats are defined using the corresponding transformer and the `Id` monad. This is reassuring as it confirms that the APIs for monads and transformers are identical. `Reader`, `Writer`, and `State` are all defined in this way:

```
type Reader[E, A] = ReaderT[Id, E, A] // = Kleisli[Id, E, A]
type Writer[W, A] = WriterT[Id, W, A]
type State[S, A]  = StateT[Id, S, A]
```

In other cases monad transformers are defined separately to their corresponding monads. In these cases, the methods of the transformer tend to mirror the methods on the monad. For example, `OptionT` defines `getOrElse`, and `EitherT` defines `fold`, `bimap`, `swap`, and other useful methods.

7.3.5 Usage Patterns

Widespread use of monad transformers is sometimes difficult because they fuse monads together in predefined ways. Without careful thought, we can end up having to unpack and repack monads in different configurations to operate on them in different contexts.

We can cope with this in multiple ways. One approach involves creating a single “super stack” and sticking to it throughout our code base. This works if the code is simple and largely uniform in nature. For example, in a web application, we could decide that all request handlers are asynchronous and all can fail with the same set of HTTP error codes. We could design a custom ADT representing the errors and use a fusion `Future` and `Either` everywhere in our code:

```
sealed abstract class HttpError
final case class NotFound(item: String) extends HttpError
final case class BadRequest(msg: String) extends HttpError
// etc...

type FutureEither[A] = EitherT[Future, HttpError, A]
```

The “super stack” approach starts to fail in larger, more heterogeneous code bases where different stacks make sense in different contexts. Another design pattern that makes more sense in these contexts uses monad transformers as local “glue code”. We expose untransformed stacks at module boundaries, transform them to operate on them locally, and untransform them before passing them on. This allows each module of code to make its own decisions about which transformers to use:

```
import cats.data.Writer

type Logged[A] = Writer[List[String], A]

// Methods generally return untransformed stacks:
def parseNumber(str: String): Logged[Option[Int]] =
  util.Try(str.toInt).toOption match {
    case Some(num) => Writer(List(s"Read $str"), Some(num))
    case None       => Writer(List(s"Failed on $str"), None)
  }

// Consumers use monad transformers locally to simplify composition:
def addAll(a: String, b: String, c: String): Logged[Option[Int]] = {
  import cats.data.OptionT

  val result = for {
    a <- OptionT(parseNumber(a))
    b <- OptionT(parseNumber(b))
    c <- OptionT(parseNumber(c))
  } yield a + b + c

  result.value
}

// This approach doesn't force OptionT on other users' code:
val result1 = addAll("1", "2", "3")
// result1: WriterT[Id, List[String], Option[Int]] = WriterT(
//   run = (List("Read 1", "Read 2", "Read 3"), Some(value = 6))
// )
val result2 = addAll("1", "a", "3")
// result2: WriterT[Id, List[String], Option[Int]] = WriterT(
//   run = (List("Read 1", "Failed on a"), None)
// )
```

Unfortunately, there aren't one-size-fits-all approaches to working with monad transformers. The best approach for you may depend on a lot of factors: the size and experience of your team, the complexity of your code base, and so on. You may need to experiment and gather feedback from colleagues to determine whether monad transformers are a good fit.

7.4 Exercise: Monads: Transform and Roll Out

The Autobots, well-known robots in disguise, frequently send messages during battle requesting the power levels of their team mates. This helps them coordinate strategies and launch devastating attacks. The message sending method looks like this:

```
def getPowerLevel(autobot: String): Response[Int] =  
???
```

Transmissions take time in Earth's viscous atmosphere, and messages are occasionally lost due to satellite malfunction or sabotage by pesky Decepticons². Responses are therefore represented as a stack of monads:

```
type Response[A] = Future[Either[String, A]]
```

Optimus Prime is getting tired of the nested for comprehensions in his neural matrix. Help him by rewriting `Response` using a monad transformer.

See the solution

Now test the code by implementing `getPowerLevel` to retrieve data from a set of imaginary allies. Here's the data we'll use:

```
val powerLevels = Map(  
  "Jazz"      -> 6,  
  "Bumblebee" -> 8,  
  "Hot Rod"   -> 10
```

²It is a well known fact that Autobot neural nets are implemented in Scala. Decepticon brains are, of course, dynamically typed.

```
)
```

If an Autobot isn't in the `powerLevels` map, return an error message reporting that they were unreachable. Include the `name` in the message for good effect.

See the solution

Two autobots can perform a special move if their combined power level is greater than 15. Write a second method, `canSpecialMove`, that accepts the names of two allies and checks whether a special move is possible. If either ally is unavailable, fail with an appropriate error message:

```
def canSpecialMove(ally1: String, ally2: String): Response[Boolean] =  
???
```

See the solution

Finally, write a method `tacticalReport` that takes two ally names and prints a message saying whether they can perform a special move:

```
def tacticalReport(ally1: String, ally2: String): String =  
???
```

See the solution

You should be able to use `report` as follows:

```
tacticalReport("Jazz", "Bumblebee")  
// res13: String = "Jazz and Bumblebee need a recharge."  
tacticalReport("Bumblebee", "Hot Rod")  
// res14: String = "Bumblebee and Hot Rod are ready to roll out!"  
tacticalReport("Jazz", "Ironhide")  
// res15: String = "Comms error: Ironhide unreachable"
```

7.5 Summary

In this chapter we introduced monad transformers, which eliminate the need for nested for comprehensions and pattern matching when working with “stacks” of nested monads.

Each monad transformer, such as `FutureT`, `OptionT` or `EitherT`, provides the code needed to merge its related monad with other monads. The transformer is a data structure that wraps a monad stack, equipping it with `map` and `flatMap` methods that unpack and repack the whole stack.

The type signatures of monad transformers are written from the inside out, so an `EitherT[Option, String, A]` is a wrapper for an `Option[Either[String, A]]`. It is often useful to use type aliases when writing transformer types for deeply nested monads.

With this look at monad transformers, we have now covered everything we need to know about monads and the sequencing of computations using `flatMap`. In the next chapter we will switch tack and discuss two new type classes, `Semigroupal` and `Applicative`, that support new kinds of operation such as zipping independent values within a context.

Chapter 8

Semigroupal and Applicative

In previous chapters we saw how functors and monads let us sequence operations using `map` and `flatMap`. While functors and monads are both immensely useful abstractions, there are certain types of program flow that they cannot represent.

One such example is form validation. When we validate a form we want to return *all* the errors to the user, not stop on the first error we encounter. If we model this with a monad like `Either`, we fail fast and lose errors. For example, the code below fails on the first call to `parseInt` and doesn't go any further:

```
import cats.syntax.either._ // for catchOnly

def parseInt(str: String): Either[String, Int] =
  Either.catchOnly[NumberFormatException](str.toInt).
    leftMap(_ => s"Couldn't read $str")

for {
  a <- parseInt("a")
  b <- parseInt("b")
  c <- parseInt("c")
} yield (a + b + c)
// res0: Either[String, Int] = Left(value = "Couldn't read a")
```

Another example is the concurrent evaluation of `Futures`. If we have several

long-running independent tasks, it makes sense to execute them concurrently. However, monadic comprehension only allows us to run them in sequence. `map` and `flatMap` aren't quite capable of capturing what we want because they make the assumption that each computation is *dependent* on the previous one:

```
// context2 is dependent on value1:  
context1.flatMap(value1 => context2)
```

The calls to `parseInt` and `Future.apply` above are *independent* of one another, but `map` and `flatMap` can't exploit this. We need a weaker construct—one that doesn't guarantee sequencing—to achieve the result we want. In this chapter we will look at three type classes that support this pattern:

- Semigroupal encompasses the notion of composing pairs of contexts. Cats provides a `cats.syntax.apply` module that makes use of Semigroupal and Functor to allow users to sequence functions with multiple arguments.
- Parallel converts types with a Monad instance to a related type with a Semigroupal instance.
- Applicative extends Semigroupal and Functor. It provides a way of applying functions to parameters within a context. Applicative is the source of the `pure` method we introduced in Chapter 6.

Applicatives are often formulated in terms of function application, instead of the semigroupal formulation that is emphasised in Cats. This alternative formulation provides a link to other libraries and languages such as Scalaz and Haskell. We'll take a look at different formulations of Applicative, as well as the relationships between Semigroupal, Functor, Applicative, and Monad, towards the end of the chapter.

8.1 Semigroupal

`cats.Semigroupal` is a type class that allows us to combine contexts¹. If we

¹It

have two objects of type $F[A]$ and $F[B]$, a `Semigroupal[F]` allows us to combine them to form an $F[(A, B)]$. Its definition in Cats is:

```
trait Semigroupal[F[_]] {  
    def product[A, B](fa: F[A], fb: F[B]): F[(A, B)]  
}
```

As we discussed at the beginning of this chapter, the parameters `fa` and `fb` are independent of one another: we can compute them in either order before passing them to `product`. This is in contrast to `flatMap`, which imposes a strict order on its parameters. This gives us more freedom when defining instances of `Semigroupal` than we get when defining `Monads`.

is also the winner of Underscore's 2017 award for the most difficult functional programming term to work into a coherent English sentence.

8.1.1 Joining Two Contexts

While `Semigroup` allows us to join values, `Semigroupal` allows us to join contexts. Let's join some `Options` as an example:

```
import cats.Semigroupal  
import cats.instances.option._ // for Semigroupal  
  
Semigroupal[Option].product(Some(123), Some("abc"))  
// res1: Option[Tuple2[Int, String]] = Some(value = (123, "abc"))
```

If both parameters are instances of `Some`, we end up with a tuple of the values within. If either parameter evaluates to `None`, the entire result is `None`:

```
Semigroupal[Option].product(None, Some("abc"))  
// res2: Option[Tuple2[Nothing, String]] = None  
Semigroupal[Option].product(Some(123), None)  
// res3: Option[Tuple2[Int, Nothing]] = None
```

8.1.2 Joining Three or More Contexts

The companion object for `Semigroupal` defines a set of methods on top of `product`. For example, the methods `tuple2` through `tuple22` generalise `product` to different arities:

```
import cats.instances.option._ // for Semigroupal

Semigroupal.tuple3(Option(1), Option(2), Option(3))
// res4: Option[Tuple3[Int, Int, Int]] = Some(value = (1, 2, 3))
Semigroupal.tuple3(Option(1), Option(2), Option.empty[Int])
// res5: Option[Tuple3[Int, Int, Int]] = None
```

The methods `map2` through `map22` apply a user-specified function to the values inside 2 to 22 contexts:

```
Semigroupal.map3(Option(1), Option(2), Option(3))(_ + _ + _)
// res6: Option[Int] = Some(value = 6)

Semigroupal.map2(Option(1), Option.empty[Int])(_ + _)
// res7: Option[Int] = None
```

There are also methods `contramap2` through `contramap22` and `imap2` through `imap22`, that require instances of `Contravariant` and `Invariant` respectively.

8.1.3 Semigroupal Laws

There is only one law for `Semigroupal`: the `product` method must be associative.

```
product(a, product(b, c)) == product(product(a, b), c)
```

8.2 Apply Syntax

Cats provides a convenient *apply syntax* that provides a shorthand for the methods described above. We import the syntax from `cats.syntax.apply`. Here's an example:

```
import cats.instances.option._ // for Semigroupal
import cats.syntax.apply._    // for tupled and mapN
```

The `tupled` method is implicitly added to the tuple of `Option`s. It uses the `Semigroupal` for `Option` to zip the values inside the `Options`, creating a single `Option` of a tuple:

```
(Option(123), Option("abc")).tupled
// res8: Option[Tuple2[Int, String]] = Some(value = (123, "abc"))
```

We can use the same trick on tuples of up to 22 values. Cats defines a separate `tupled` method for each arity:

```
(Option(123), Option("abc"), Option(true)).tupled
// res9: Option[Tuple3[Int, String, Boolean]] = Some(
//   value = (123, "abc", true)
// )
```

In addition to `tupled`, Cats' apply syntax provides a method called `mapN` that accepts an implicit `Functor` and a function of the correct arity to combine the values.

```
final case class Cat(name: String, born: Int, color: String)

(
  Option("Garfield"),
  Option(1978),
  Option("Orange & black")
).mapN(Cat.apply)
// res10: Option[Cat] = Some(
//   value = Cat(name = "Garfield", born = 1978, color = "Orange &
//   black")
// )
```

Of all the methods mentioned here, it is most common to use `mapN`.

Internally `mapN` uses the `Semigroupal` to extract the values from the `Option` and the `Functor` to apply the values to the function.

It's nice to see that this syntax is type checked. If we supply a function that accepts the wrong number or types of parameters, we get a compile error:

```
val add: (Int, Int) => Int = (a, b) => a + b
// add: Function2[Int, Int, Int] = repl.
    MdocSession$MdocApp0$$Lambda$15553/0x00007f2d466f9de8@dc56990

(Option(1), Option(2), Option(3)).mapN(add)
// error:
// ':' expected, but '(' found
//   Option("Garfield"),
//   ^
// error:
// ':' expected, but '(' found
//   Option(1978),
//   ^
// error:
// ':' expected, but '(' found
//   Option("Orange & black")
//   ^
// error:
// end of statement expected but '.' found
// ).mapN(Cat.apply)
// ^
// error:
// Found:     (repl.MdocSession.MdocApp0.add : (Int, Int) => Int)
// Required: (Int, Int, Int) => Nothing
// (Option(1), Option(2), Option(3)).mapN(add)
//                                         ^^^

(Option("cats"), Option(true)).mapN(add)
// error:
// ':' expected, but '(' found
//   Option("Garfield"),
//   ^
// error:
// ':' expected, but '(' found
//   Option(1978),
//   ^
// error:
// ':' expected, but '(' found
//   Option("Orange & black")
//   ^
// error:
// end of statement expected but '.' found
// ).mapN(Cat.apply)
```

```
// ^
// error:
// Found:    (repl.MdocSession.MdocApp0.add : (Int, Int) => Int)
// Required: (String, Boolean) => Nothing
// (Option("cats"), Option(true)).mapN(add)
// ^^^
```

8.2.1 Fancy Functors and Apply Syntax

Apply syntax also has `contramapN` and `imapN` methods that accept Contravariant and Invariant functors (Section 5.6). For example, we can combine Monoids using Invariant. Here's an example:

```
import cats.Monoid
import cats.instances.int._          // for Monoid
import cats.instances.invariant._   // for Semigroupal
import cats.instances.list._        // for Monoid
import cats.instances.string._     // for Monoid
import cats.syntax.apply._         // for imapN

final case class Cat(
  name: String,
  yearOfBirth: Int,
  favoriteFoods: List[String]
)

val tupleToCat: (String, Int, List[String]) => Cat =
  Cat.apply _

val catToTuple: Cat => (String, Int, List[String]) =
  cat => (cat.name, cat.yearOfBirth, cat.favoriteFoods)

implicit val catMonoid: Monoid[Cat] = (
  Monoid[String],
  Monoid[Int],
  Monoid[List[String]]
).imapN(tupleToCat)(catToTuple)
```

Our `Monoid` allows us to create “empty” `Cats`, and add `Cats` together using the syntax from Chapter 4:

```
import cats.syntax.semigroup._ // for |+|  
  
val garfield = Cat("Garfield", 1978, List("Lasagne"))  
val heathcliff = Cat("Heathcliff", 1988, List("Junk Food"))  
  
garfield |+| heathcliff  
// res14: Cat = Cat(  
//   name = "GarfieldHeathcliff",  
//   yearOfBirth = 3966,  
//   favoriteFoods = List("Lasagne", "Junk Food")  
// )
```

8.3 Semigroupal Applied to Different Types

Semigroupal doesn't always provide the behaviour we expect, particularly for types that also have instances of `Monad`. We have seen the behaviour of the Semigroupal for `Option`. Let's look at some examples for other types.

Future

The semantics for `Future` provide parallel as opposed to sequential execution:

```
import cats.Semigroupal  
import cats.instances.future._ // for Semigroupal  
import scala.concurrent._  
import scala.concurrent.duration._  
import scala.concurrent.ExecutionContext.Implicits.global  
  
val futurePair = Semigroupal[Future].  
  product(Future("Hello"), Future(123))  
  
Await.result(futurePair, 1.second)  
// res0: Tuple2[String, Int] = ("Hello", 123)
```

The two `Futures` start executing the moment we create them, so they are already calculating results by the time we call `product`. We can use `apply` syntax to zip fixed numbers of `Futures`:

```
import cats.syntax.apply._ // for mapN

case class Cat(
  name: String,
  yearOfBirth: Int,
  favoriteFoods: List[String]
)

val futureCat = (
  Future("Garfield"),
  Future(1978),
  Future(List("Lasagne"))
).mapN(Cat.apply)

Await.result(futureCat, 1.second)
// res1: Cat = Cat(
//   name = "Garfield",
//   yearOfBirth = 1978,
//   favoriteFoods = List("Lasagne")
// )
```

List

Combining `Lists` with `Semigroupal` produces some potentially unexpected results. We might expect code like the following to `zip` the lists, but we actually get the cartesian product of their elements:

```
import cats.Semigroupal
import cats.instances.list._ // for Semigroupal

Semigroupal[List].product(List(1, 2), List(3, 4))
// res2: List[Tuple2[Int, Int]] = List((1, 3), (1, 4), (2, 3), (2, 4))
```

This is perhaps surprising. Zipping lists tends to be a more common operation. We'll see why we get this behaviour in a moment.

Either

We opened this chapter with a discussion of fail-fast versus accumulating error-handling. We might expect `product` applied to `Either` to accumulate errors instead of fail fast. Again, perhaps surprisingly, we find that `product` implements the same fail-fast behaviour as `flatMap`:

```

import cats.instances.either._ // for Semigroupal

type ErrorOr[A] = Either[Vector[String], A]

Semigroupal[ErrorOr].product(
  Left(Vector("Error 1")),
  Left(Vector("Error 2")))
)
// res3: Either[Vector[String], Tuple2[Nothing, Nothing]] = Left(
//   value = Vector("Error 1"))
// )

```

In this example `product` sees the first failure and stops, even though it is possible to examine the second parameter and see that it is also a failure.

8.3.1 Semigroupal Applied to Monads

The reason for the surprising results for `List` and `Either` is that they are both monads. If we have a monad we can implement `product` as follows.

```

import cats.Monad
import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatmap

def product[F[_]: Monad, A, B](fa: F[A], fb: F[B]): F[(A,B)] =
  fa.flatMap(a =>
    fb.map(b =>
      (a, b)
    )
  )

```

It would be very strange if we had different semantics for `product` depending on how we implemented it. To ensure consistent semantics, Cats' `Monad` (which extends `Semigroupal`) provides a standard definition of `product` in terms of `map` and `flatMap` as we showed above.

Even our results for `Future` are a trick of the light. `flatMap` provides sequential ordering, so `product` provides the same. The parallel execution we observe occurs because our constituent `Futures` start running before we call `product`. This is equivalent to the classic `create-then-flatMap` pattern:

```
val a = Future("Future 1")
val b = Future("Future 2")

for {
  x <- a
  y <- b
} yield (x, y)
```

So why bother with `Semigroupal` at all? The answer is that we can create useful data types that have instances of `Semigroupal` (and `Applicative`) but not `Monad`. This frees us to implement `product` in different ways. We'll examine this further in a moment when we look at an alternative data type for error handling.

8.3.1.1 Exercise: The Product of Lists

Why does `product` for `List` produce the Cartesian product? We saw an example above. Here it is again.

```
Semigroupal[List].product(List(1, 2), List(3, 4))
// res5: List[Tuple2[Int, Int]] = List((1, 3), (1, 4), (2, 3), (2, 4))
```

We can also write this in terms of `tupled`.

```
(List(1, 2), List(3, 4)).tupled
// res6: List[Tuple2[Int, Int]] = List((1, 3), (1, 4), (2, 3), (2, 4))
```

See the solution

8.4 Parallel

In the previous section we saw that when call `product` on a type that has a `Monad` instance we get sequential semantics. This makes sense from the point-of-view of keeping consistency with implementations of `product` in terms of `flatMap` and `map`. However it's not always what we want. The `Parallel` type

class, and its associated syntax, allows us to access alternate semantics for certain monads.

We've seen how the product method on Either stops at the first error.

```
import cats.Semigroupal
import cats.instances.either._ // for Semigroupal

type ErrorOr[A] = Either[Vector[String], A]
val error1: ErrorOr[Int] = Left(Vector("Error 1"))
val error2: ErrorOr[Int] = Left(Vector("Error 2"))

Semigroupal[ErrorOr].product(error1, error2)
// res0: Either[Vector[String], Tuple2[Int, Int]] = Left(
//   value = Vector("Error 1")
// )
```

We can also write this using tupled as a short-cut.

```
import cats.syntax.apply._ // for tupled
import cats.instances.vector._ // for Semigroup on Vector

(error1, error2).tupled
// res1: Either[Vector[String], Tuple2[Int, Int]] = Left(
//   value = Vector("Error 1")
// )
```

To collect all the errors we simply replace tupled with its "parallel" version called parTupled.

```
import cats.syntax.parallel._ // for parTupled

(error1, error2).parTupled
// res2: Either[Vector[String], Tuple2[Int, Int]] = Left(
//   value = Vector("Error 1", "Error 2")
// )
```

Notice that both errors are returned! This behaviour is not special to using Vector as the error type. Any type that has a Semigroup instance will work. For example, here we use List instead.

```
import cats.instances.list._ // for Semigroup on List

type ErrorOrList[A] = Either[List[String], A]
val errStr1: ErrorOrList[Int] = Left(List("error 1"))
val errStr2: ErrorOrList[Int] = Left(List("error 2"))

(errStr1, errStr2).parTupled
// res3: Either[List[String], Tuple2[Int, Int]] = Left(
//   value = List("error 1", "error 2")
// )
```

There are many syntax methods provided by Parallel for methods on Semigroupal and related types, but the most commonly used is parMapN. Here's an example of parMapN in an error handling situation.

```
val success1: ErrorOr[Int] = Right(1)
val success2: ErrorOr[Int] = Right(2)
val addTwo = (x: Int, y: Int) => x + y

(error1, error2).parMapN(addTwo)
// res4: Either[Vector[String], Int] = Left(
//   value = Vector("Error 1", "Error 2")
// )
(success1, success2).parMapN(addTwo)
// res5: Either[Vector[String], Int] = Right(value = 3)
```

Let's dig into how Parallel works. The definition below is the core of Parallel.

```
trait Parallel[M[_]] {
  type F[_]

  def applicative: Applicative[F]
  def monad: Monad[M]
  def parallel: ~>[M, F]
}
```

This tells us if there is a Parallel instance for some type constructor M then:

- there must be a Monad instance for M;

- there is a related type constructor F that has an Applicative instance; and
- we can convert M to F .

We haven't seen \sim before. It's a type alias for `FunctionK` and is what performs the conversion from M to F . A normal function $A \Rightarrow B$ converts values of type A to values of type B . Remember that M and F are not types; they are type constructors. A `FunctionK` $M \sim F$ is a function from a value with type $M[A]$ to a value with type $F[A]$. Let's see a quick example by defining a `FunctionK` that converts an `Option` to a `List`.

```
import cats.arrow.FunctionK

object optionToList extends FunctionK[Option, List] {
  def apply[A](fa: Option[A]): List[A] =
    fa match {
      case None    => List.empty[A]
      case Some(a) => List(a)
    }
}

optionToList(Some(1))
// res6: List[Int] = List(1)
optionToList(None)
// res7: List[Nothing] = List()
```

As the type parameter A is generic a `FunctionK` cannot inspect any values contained with the type constructor M . The conversion must be performed purely in terms of the structure of the type constructors M and F . We can in `optionToList` above this is indeed the case.

So in summary, `Parallel` allows us to take a type that has a monad instance and convert it to some related type that instead has an applicative (or semigroupal) instance. This related type will have some useful alternate semantics. We've seen the case above where the related applicative for `Either` allows for accumulation of errors instead of fail-fast semantics.

Now we've seen `Parallel` it's time to finally learn about `Applicative`.

8.4.0.1 Exercise: Parallel List

Does List have a Parallel instance? If so, what does the Parallel instance do?

See the solution

8.5 Apply and Applicative

Semigroupals aren't mentioned frequently in the wider functional programming literature. They provide a subset of the functionality of a related type class called an *applicative functor* ("applicative" for short).

Semigroupal and Applicative effectively provide alternative encodings of the same notion of joining contexts. Both encodings are introduced in the [same 2008 paper](#) by Conor McBride and Ross Paterson².

Cats models applicatives using two type classes. The first, `cats.Apply`, extends Semigroupal and Functor and adds an `ap` method that applies a parameter to a function within a context. The second, `cats.Applicative`, extends `Apply` and adds the `pure` method introduced in Chapter 6. Here's a simplified definition in code:

```
trait Apply[F[_]] extends Semigroupal[F] with Functor[F] {
  def ap[A, B](ff: F[A => B])(fa: F[A]): F[B]

  def product[A, B](fa: F[A], fb: F[B]): F[(A, B)] =
    ap(map(fa)(a => (b: B) => (a, b)))(fb)
}

trait Applicative[F[_]] extends Apply[F] {
  def pure[A](a: A): F[A]
}
```

Breaking this down, the `ap` method applies a parameter `fa` to a function `ff` within a context `F[_]`. The `product` method from `Semigroupal` is defined in terms of `ap` and `map`.

²Semigroupal is referred to as "monoidal" in the paper.

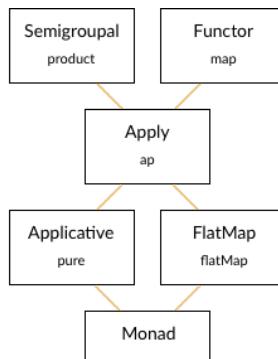

Figure 8.1: Monad type class hierarchy

Don't worry too much about the implementation of `product`—it's difficult to read and the details aren't particularly important. The main point is that there is a tight relationship between `product`, `ap`, and `map` that allows any one of them to be defined in terms of the other two.

`Applicative` also introduces the `pure` method. This is the same `pure` we saw in `Monad`. It constructs a new applicative instance from an unwrapped value. In this sense, `Applicative` is related to `Apply` as `Monoid` is related to `Semigroup`.

8.5.1 The Hierarchy of Sequencing Type Classes

With the introduction of `Apply` and `Applicative`, we can zoom out and see a whole family of type classes that concern themselves with sequencing computations in different ways. Figure 8.1 shows the relationship between the type classes covered in this book³.

Each type class in the hierarchy represents a particular set of sequencing semantics, introduces a set of characteristic methods, and defines the functionality of its supertypes in terms of them:

- every monad is an applicative;
- every applicative a semigroupal;

³See [Rob Norris' infographic](#) for a complete picture.

- and so on.

Because of the lawful nature of the relationships between the type classes, the inheritance relationships are constant across all instances of a type class. `Apply` defines `product` in terms of `ap` and `map`; `Monad` defines `product`, `ap`, and `map`, in terms of `pure` and `flatMap`.

To illustrate this let's consider two hypothetical data types:

- `Foo` is a monad. It has an instance of the `Monad` type class that implements `pure` and `flatMap` and inherits standard definitions of `product`, `map`, and `ap`;
- `Bar` is an applicative functor. It has an instance of `Applicative` that implements `pure` and `ap` and inherits standard definitions of `product` and `map`.

What can we say about these two data types without knowing more about their implementation?

We know strictly more about `Foo` than `Bar`: `Monad` is a subtype of `Applicative`, so we can guarantee properties of `Foo` (namely `flatMap`) that we cannot guarantee with `Bar`. Conversely, we know that `Bar` may have a wider range of behaviours than `Foo`. It has fewer laws to obey (no `flatMap`), so it can implement behaviours that `Foo` cannot.

This demonstrates the classic trade-off of power (in the mathematical sense) versus constraint. The more constraints we place on a data type, the more guarantees we have about its behaviour, but the fewer behaviours we can model.

Monads happen to be a sweet spot in this trade-off. They are flexible enough to model a wide range of behaviours and restrictive enough to give strong guarantees about those behaviours. However, there are situations where monads aren't the right tool for the job. Sometimes we want Thai food, and burritos just won't satisfy.

Whereas monads impose a strict *sequencing* on the computations they model, applicatives and semigroupals impose no such restriction. This puts them in a

different sweet spot in the hierarchy. We can use them to represent classes of parallel / independent computations that monads cannot.

We choose our semantics by choosing our data structures. If we choose a monad, we get strict sequencing. If we choose an applicative, we lose the ability to `flatMap`. This is the trade-off enforced by the consistency laws. So choose your types carefully!

8.6 Summary

While monads and functors are the most widely used sequencing data types we've covered in this book, semigroupals and applicatives are the most general. These type classes provide a generic mechanism to combine values and apply functions within a context, from which we can fashion monads and a variety of other combinators.

Semigroupal and Applicative are most commonly used as a means of combining independent values such as the results of validation rules. Cats provides the `Validated` type for this specific purpose, along with `apply` syntax as a convenient way to express the combination of rules.

We have almost covered all of the functional programming concepts on our agenda for this book. The next chapter covers `Traverse` and `Foldable`, two powerful type classes for converting between data types. After that we'll look at several case studies that bring together all of the concepts from Part I.

Chapter 9

Foldable and Traverse

In this chapter we'll look at two type classes that capture iteration over collections:

- `Foldable` abstracts the familiar `foldLeft` and `foldRight` operations;
- `Traverse` is a higher-level abstraction that uses `Applicatives` to iterate with less pain than folding.

We'll start by looking at `Foldable`, and then examine cases where folding becomes complex and `Traverse` becomes convenient.

9.1 Foldable

The `Foldable` type class captures the `foldLeft` and `foldRight` methods we're used to in sequences like `Lists`, `Vectors`, and `Streams`. Using `Foldable`, we can write generic folds that work with a variety of sequence types. We can also invent new sequences and plug them into our code. `Foldable` gives us great use cases for `Monoids` and the `Eval` monad.

9.1.1 Folds and Folding

Let's start with a quick recap of the general concept of folding. We supply an *accumulator* value and a *binary function* to combine it with each item in the sequence:

```
def show[A](list: List[A]): String =
  list.foldLeft("nil")((accum, item) => s"$item then $accum")

show(Nil)
// res0: String = "nil"

show(List(1, 2, 3))
// res1: String = "3 then 2 then 1 then nil"
```

The `foldLeft` method works recursively down the sequence. Our binary function is called repeatedly for each item, the result of each call becoming the accumulator for the next. When we reach the end of the sequence, the final accumulator becomes our final result.

Depending on the operation we're performing, the order in which we fold may be important. Because of this there are two standard variants of fold:

- `foldLeft` traverses from “left” to “right” (start to finish);
- `foldRight` traverses from “right” to “left” (finish to start).

Figure 9.1 illustrates each direction.

`foldLeft` and `foldRight` are equivalent if our binary operation is associative. For example, we can sum a `List[Int]` by folding in either direction, using `0` as our accumulator and addition as our operation:

```
List(1, 2, 3).foldLeft(0)(_ + _)
// res2: Int = 6
List(1, 2, 3).foldRight(0)(_ + _)
// res3: Int = 6
```

If we provide a non-associative operator the order of evaluation makes a difference. For example, if we fold using subtraction, we get different results in each direction:

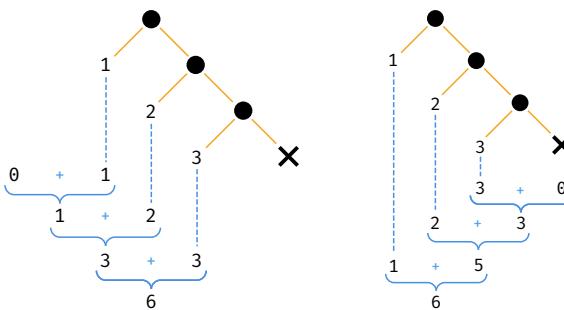

Figure 9.1: Illustration of foldLeft and foldRight

```
List(1, 2, 3).foldLeft(0)(_ - _)
// res4: Int = -6
List(1, 2, 3).foldRight(0)(_ - _)
// res5: Int = 2
```

9.1.2 Exercise: Reflecting on Folds

Try using `foldLeft` and `foldRight` with an empty list as the accumulator and `::` as the binary operator. What results do you get in each case?

See the solution

9.1.3 Exercise: Scaf-fold-ing Other Methods

`foldLeft` and `foldRight` are very general methods. We can use them to implement many of the other high-level sequence operations we know. Prove this to yourself by implementing substitutes for `List`'s `map`, `flatMap`, `filter`, and `sum` methods in terms of `foldRight`.

See the solution

9.1.4 Foldable in Cats

Cats' `Foldable` abstracts `foldLeft` and `foldRight` into a type class. Instances of `Foldable` define these two methods and inherit a host of derived methods.

Cats provides out-of-the-box instances of Foldable for a handful of Scala data types: `List`, `Vector`, `LazyList`, and `Option`.

We can summon instances as usual using `Foldable.apply` and call their implementations of `foldLeft` directly. Here is an example using `List`:

```
import cats.Foldable
import cats.instances.list._ // for Foldable

val ints = List(1, 2, 3)

Foldable[List].foldLeft(ints, 0)(_ + _)
// res0: Int = 6
```

Other sequences like `Vector` and `LazyList` work in the same way. Here is an example using `Option`, which is treated like a sequence of zero or one elements:

```
import cats.instances.option._ // for Foldable

val maybeInt = Option(123)

Foldable[Option].foldLeft(maybeInt, 10)(_ * _)
// res1: Int = 1230
```

9.1.4.1 Folding Right

`Foldable` defines `foldRight` differently to `foldLeft`, in terms of the `Eval` monad:

```
def foldRight[A, B](fa: F[A], lb: Eval[B])
                  (f: (A, Eval[B]) => Eval[B]): Eval[B]
```

Using `Eval` means folding is always *stack safe*, even when the collection's default definition of `foldRight` is not. For example, the default implementation of `foldRight` for `LazyList` is not stack safe. The longer the lazy list, the larger the stack requirements for the fold. A sufficiently large lazy list will trigger a `StackOverflowError`:

```
import cats.Eval
import cats.Foldable

def bigData = (1 to 100000).to(LazyList)

bigData.foldRight(0L)(_ + _)
// java.lang.StackOverflowError ...
```

Using `Foldable` forces us to use stack safe operations, which fixes the overflow exception:

```
import cats.instances.lazyList._ // for Foldable

val eval: Eval[Long] =
  Foldable[LazyList].  

    foldRight(bigData, Eval.now(0L)) { (num, eval) =>
      eval.map(_ + num)
    }

eval.value
// res3: Long = 5000050000L
```

Stack Safety in the Standard Library

Stack safety isn't typically an issue when using the standard library. The most commonly used collection types, such as `List` and `Vector`, provide stack safe implementations of `foldRight`:

```
(1 to 100000).toList.foldRight(0L)(_ + _)
// res4: Long = 5000050000L
(1 to 100000).toVector.foldRight(0L)(_ + _)
// res5: Long = 5000050000L
```

We've called out `Stream` because it is an exception to this rule. Whatever data type we're using, though, it's useful to know that `Eval` has our back.

9.1.4.2 Folding with Monoids

`Foldable` provides us with a host of useful methods defined on top of `foldLeft`. Many of these are facsimiles of familiar methods from the standard library: `find`, `exists`, `forall`, `toList`, `isEmpty`, `nonEmpty`, and so on:

```
Foldable[Option].nonEmpty(Option(42))
// res6: Boolean = true

Foldable[List].find(List(1, 2, 3))(_ % 2 == 0)
// res7: Option[Int] = Some(value = 2)
```

In addition to these familiar methods, Cats provides two methods that make use of Monoids:

- `combineAll` (and its alias `fold`) combines all elements in the sequence using their Monoid;
- `foldMap` maps a user-supplied function over the sequence and combines the results using a Monoid.

For example, we can use `combineAll` to sum over a `List[Int]`:

```
import cats.instances.int._ // for Monoid

Foldable[List].combineAll(List(1, 2, 3))
// res8: Int = 6
```

Alternatively, we can use `foldMap` to convert each `Int` to a `String` and concatenate them:

```
import cats.instances.string._ // for Monoid

Foldable[List].foldMap(List(1, 2, 3))(_.toString)
// res9: String = "123"
```

Finally, we can compose `Foldables` to support deep traversal of nested sequences:

```
import cats.instances.vector._ // for Monoid

val ints = List(Vector(1, 2, 3), Vector(4, 5, 6))

(Foldable[List] compose Foldable[Vector]).combineAll(ints)
// res11: Int = 21
```

9.1.4.3 Syntax for Foldable

Every method in `Foldable` is available in syntax form via `cats.syntax.foldable`. In each case, the first argument to the method on `Foldable` becomes the receiver of the method call:

```
import cats.syntax.foldable._ // for combineAll and foldMap

List(1, 2, 3).combineAll
// res12: Int = 6

List(1, 2, 3).foldMap(_.toString)
// res13: String = "123"
```

Explicits over Implicits

Remember that Scala will only use an instance of `Foldable` if the method isn't explicitly available on the receiver. For example, the following code will use the version of `foldLeft` defined on `List`:

```
List(1, 2, 3).foldLeft(0)(_ + _)
// res14: Int = 6
```

whereas the following generic code will use `Foldable`:

```
def sum[F[_]: Foldable](values: F[Int]): Int =
  values.foldLeft(0)(_ + _)
```

We typically don't need to worry about this distinction. It's a feature! We call the method we want and the compiler uses a Foldable when needed to ensure our code works as expected. If we need a stack-safe implementation of `foldRight`, using `Eval` as the accumulator is enough to force the compiler to select the method from Cats.

9.2 Traverse

`foldLeft` and `foldRight` are flexible iteration methods but they require us to do a lot of work to define accumulators and combinator functions. The `Traverse` type class is a higher level tool that leverages `Applicatives` to provide a more convenient, more lawful, pattern for iteration.

9.2.1 Traversing with Futures

We can demonstrate `Traverse` using the `Future.traverse` and `Future.sequence` methods in the Scala standard library. These methods provide `Future`-specific implementations of the traverse pattern. As an example, suppose we have a list of server hostnames and a method to poll a host for its uptime:

```
import scala.concurrent._  
import scala.concurrent.duration._  
import scala.concurrent.ExecutionContext.Implicits.global  
  
val hostnames = List(  
    "alpha.example.com",  
    "beta.example.com",  
    "gamma.demo.com"  
)  
  
def getUptime(hostname: String): Future[Int] =  
    Future(hostname.length * 60) // just for demonstration
```

Now, suppose we want to poll all of the hosts and collect all of their uptimes. We can't simply `map` over `hostnames` because the result—a `List[Future[Int]]`—would contain more than one `Future`. We need to reduce the results to a single

Future to get something we can block on. Let's start by doing this manually using a fold:

```
val allUptimes: Future[List[Int]] =  
  hostnames.foldLeft(Future(List.empty[Int])) {  
    (accum, host) =>  
      val uptime = getUptime(host)  
      for {  
        accum <- accum  
        uptime <- uptime  
      } yield accum :+ uptime  
  }  
  
Await.result(allUptimes, 1.second)  
// res0: List[Int] = List(1020, 960, 840)
```

Intuitively, we iterate over hostnames, call `func` for each item, and combine the results into a list. This sounds simple, but the code is fairly unwieldy because of the need to create and combine Futures at every iteration. We can improve on things greatly using `Future.traverse`, which is tailor-made for this pattern:

```
val allUptimes: Future[List[Int]] =  
  Future.traverse(hostnames)(getUptime)  
  
Await.result(allUptimes, 1.second)  
// res2: List[Int] = List(1020, 960, 840)
```

This is much clearer and more concise—let's see how it works. If we ignore distractions like `CanBuildFrom` and `ExecutionContext`, the implementation of `Future.traverse` in the standard library looks like this:

```
def traverse[A, B](values: List[A])  
  (func: A => Future[B]): Future[List[B]] =  
  values.foldLeft(Future(List.empty[B])) { (accum, host) =>  
    val item = func(host)  
    for {  
      accum <- accum  
      item <- item  
    } yield accum :+ item
```

```
}
```

This is essentially the same as our example code above. `Future.traverse` is abstracting away the pain of folding and defining accumulators and combination functions. It gives us a clean high-level interface to do what we want:

- start with a `List[A]`;
- provide a function `A => Future[B]`;
- end up with a `Future[List[B]]`.

The standard library also provides another method, `Future.sequence`, that assumes we're starting with a `List[Future[B]]` and don't need to provide an identity function:

```
object Future {  
    def sequence[B](futures: List[Future[B]]): Future[List[B]] =  
        traverse(futures)(identity)  
  
    // etc...  
}
```

In this case the intuitive understanding is even simpler:

- start with a `List[Future[A]]`;
- end up with a `Future[List[A]]`.

`Future.traverse` and `Future.sequence` solve a very specific problem: they allow us to iterate over a sequence of Futures and accumulate a result. The simplified examples above only work with Lists, but the real `Future.traverse` and `Future.sequence` work with any standard Scala collection.

Cats' Traverse type class generalises these patterns to work with any type of Applicative: `Future`, `Option`, `Validated`, and so on. We'll approach Traverse in the next sections in two steps: first we'll generalise over the Applicative, then we'll generalise over the sequence type. We'll end up with an extremely valuable tool that trivialises many operations involving sequences and other data types.

9.2.2 Traversing with Applicatives

If we squint, we'll see that we can rewrite `traverse` in terms of an `Applicative`. Our accumulator from the example above:

```
Future(List.empty[Int])
```

is equivalent to `Applicative.pure`:

```
import cats.Applicative
import cats.instances.future._    // for Applicative
import cats.syntax.applicative._ // for pure

List.empty[Int].pure[Future]
```

Our combinator, which used to be this:

```
def oldCombine(
  accum : Future[List[Int]],
  host  : String
): Future[List[Int]] = {
  val uptime = getUptime(host)
  for {
    accum  <- accum
    uptime <- uptime
  } yield accum :+ uptime
}
```

is now equivalent to `Semigroupal.combine`:

```
import cats.syntax.apply._ // for mapN

// Combining accumulator and hostname using an Applicative:
def newCombine(accum: Future[List[Int]],
               host: String): Future[List[Int]] =
  (accum, getUptime(host)).mapN(_ :+ _)
```

By substituting these snippets back into the definition of `traverse` we can generalise it to work with any `Applicative`:

```
def listTraverse[F[_]: Applicative, A, B]
  (list: List[A])(func: A => F[B]): F[List[B]] =
  list.foldLeft(List.empty[B].pure[F]) { (accum, item) =>
    (accum, func(item)).mapN(_ :+ _)
  }

def listSequence[F[_]: Applicative, B]
  (list: List[F[B]]): F[List[B]] =
  listTraverse(list)(identity)
```

We can use `listTraverse` to re-implement our uptime example:

```
val totalUptime = listTraverse(hostnames)(getUptime)

Await.result(totalUptime, 1.second)
// res5: List[Int] = List(1020, 960, 840)
```

or we can use it with other `Applicative` data types as shown in the following exercises.

9.2.2.1 Exercise: Traversing with Vectors

What is the result of the following?

```
import cats.instances.vector._ // for Applicative

listSequence(List(Vector(1, 2), Vector(3, 4)))
```

See the solution

What about a list of three parameters?

```
listSequence(List(Vector(1, 2), Vector(3, 4), Vector(5, 6)))
```

See the solution

9.2.2.2 Exercise: Traversing with Options

Here's an example that uses Options:

```
import cats.instances.option._ // for Applicative

def process(inputs: List[Int]) =
  listTraverse(inputs)(n => if(n % 2 == 0) Some(n) else None)
```

What is the return type of this method? What does it produce for the following inputs?

```
process(List(2, 4, 6))
process(List(1, 2, 3))
```

See the solution

9.2.2.3 Exercise: Traversing with Validated

Finally, here is an example that uses Validated:

```
import cats.data.Validated
import cats.instances.list._ // for Monoid

type ErrorsOr[A] = Validated[List[String], A]

def process(inputs: List[Int]): ErrorsOr[List[Int]] =
  listTraverse(inputs) { n =>
    if(n % 2 == 0) {
      Validated.valid(n)
    } else {
      Validated.invalid(List(s"$n is not even"))
    }
  }
```

What does this method produce for the following inputs?

```
process(List(2, 4, 6))
process(List(1, 2, 3))
```

See the solution

9.2.3 Traverse in Cats

Our `listTraverse` and `listSequence` methods work with any type of `Applicative`, but they only work with one type of sequence: `List`. We can generalise over different sequence types using a type class, which brings us to Cats' `Traverse`. Here's the abbreviated definition:

```
package cats

trait Traverse[F[_]] {
  def traverse[G[_]: Applicative, A, B]
    (inputs: F[A])(func: A => G[B]): G[F[B]]

  def sequence[G[_]: Applicative, B]
    (inputs: F[G[B]]): G[F[B]] =
    traverse(inputs)(identity)
}
```

Cats provides instances of `Traverse` for `List`, `Vector`, `Stream`, `Option`, `Either`, and a variety of other types. We can summon instances as usual using `Traverse`. `apply` and use the `traverse` and `sequence` methods as described in the previous section:

```
import cats.Traverse
import cats.instances.future._ // for Applicative
import cats.instances.list._ // for Traverse

val totalUptime: Future[List[Int]] =
  Traverse[List].traverse(hostnames)(getUptime)

Await.result(totalUptime, 1.second)
// res0: List[Int] = List(1020, 960, 840)

val numbers = List(Future(1), Future(2), Future(3))
```

```
val numbers2: Future[List[Int]] =  
  Traversable[List].sequence(numbers)  
  
Await.result(numbers2, 1.second)  
// res1: List[Int] = List(1, 2, 3)
```

There are also syntax versions of the methods, imported via `cats.syntax.traverse`:

```
import cats.syntax.traverse._ // for sequence and traverse  
  
val numbers3 = hostnames.traverse(getUptime)  
// numbers3: Future[List[Int]] = Future(Success(List(1020, 960, 840)))  
val numbers4 = numbers.sequence  
// numbers4: Future[List[Int]] = Future(Success(List(1, 2, 3)))  
  
Await.result(numbers3, 1.second)  
// res2: List[Int] = List(1020, 960, 840)  
Await.result(numbers4, 1.second)  
// res3: List[Int] = List(1, 2, 3)
```

As you can see, this is much more compact and readable than the `foldLeft` code we started with earlier this chapter!

9.3 Summary

In this chapter we were introduced to `Foldable` and `Traversable`, two type classes for iterating over sequences.

`Foldable` abstracts the `foldLeft` and `foldRight` methods we know from collections in the standard library. It adds stack-safe implementations of these methods to a handful of extra data types, and defines a host of situationally useful additions. That said, `Foldable` doesn't introduce much that we didn't already know.

The real power comes from `Traversable`, which abstracts and generalises the `traverse` and `sequence` methods we know from `Future`. Using these methods

we can turn an $F[G[A]]$ into a $G[F[A]]$ for any F with an instance of `Traversable` and any G with an instance of `Applicative`. In terms of the reduction we get in lines of code, `Traversable` is one of the most powerful patterns in this book. We can reduce folds of many lines down to a single `foo.traverse`.

...and with that, we've finished all of the theory in this book. There's plenty more to come, though, as we put everything we've learned into practice in a series of in-depth case studies in Part II!

Part II

Case Studies

Chapter 10

Case Study: Testing Asynchronous Code

We'll start with a straightforward case study: how to simplify unit tests for asynchronous code by making them synchronous.

Let's return to the example from Chapter 9 where we're measuring the uptime on a set of servers. We'll flesh out the code into a more complete structure. There will be two components. The first is an `UptimeClient` that polls remote servers for their uptime:

```
import scala.concurrent.Future

trait UptimeClient {
  def getUptime(hostname: String): Future[Int]
}
```

We'll also have an `UptimeService` that maintains a list of servers and allows the user to poll them for their total uptime:

```
import cats.instances.future._ // for Applicative
import cats.instances.list._  // for Traverse
import cats.syntax.traverse._ // for traverse
```

```
import scala.concurrent.ExecutionContext.Implicits.global

class UptimeService(client: UptimeClient) {
  def getTotalUptime(hostnames: List[String]): Future[Int] =
    hostnames.traverse(client.getUptime).map(_.sum)
}
```

We've modelled `UptimeClient` as a trait because we're going to want to stub it out in unit tests. For example, we can write a test client that allows us to provide dummy data rather than calling out to actual servers:

```
class TestUptimeClient(hosts: Map[String, Int]) extends UptimeClient {
  def getUptime(hostname: String): Future[Int] =
    Future.successful(hosts.getOrElse(hostname, 0))
}
```

Now, suppose we're writing unit tests for `UptimeService`. We want to test its ability to sum values, regardless of where it is getting them from. Here's an example:

```
def testTotalUptime() = {
  val hosts      = Map("host1" -> 10, "host2" -> 6)
  val client    = new TestUptimeClient(hosts)
  val service   = new UptimeService(client)
  val actual    = service.getTotalUptime(hosts.keys.toList)
  val expected = hosts.values.sum
  assert(actual == expected)
}

// error:
// Values of types concurrent.Future[Int] and Int cannot be compared
// with == or !=
// assert(actual == expected)
//           ^^^^^^^^^^^^^^
```

The code doesn't compile because we've made a classic error¹. We forgot that our application code is asynchronous. Our actual result is of type `Future[Int]` and our expected result is of type `Int`. We can't compare them directly!

¹Technically this is a *warning* not an error. It has been promoted to an error in our case because we're using the `-Xfatal-warnings` flag on scalac.

There are a couple of ways to solve this problem. We could alter our test code to accommodate the asynchronousness. However, there is another alternative. Let's make our service code synchronous so our test works without modification!

10.1 Abstracting over Type Constructors

We need to implement two versions of `UptimeClient`: an asynchronous one for use in production and a synchronous one for use in our unit tests:

```
trait RealUptimeClient extends UptimeClient {
  def getUptime(hostname: String): Future[Int]
}

trait TestUptimeClient extends UptimeClient {
  def getUptime(hostname: String): Int
}
```

The question is: what result type should we give to the abstract method in `UptimeClient`? We need to abstract over `Future[Int]` and `Int`:

```
trait UptimeClient {
  def getUptime(hostname: String): ????
}
```

At first this may seem difficult. We want to retain the `Int` part from each type but “throw away” the `Future` part in the test code. Fortunately, Cats provides a solution in terms of the *identity type*, `Id`, that we discussed way back in Section 6.3. `Id` allows us to “wrap” types in a type constructor without changing their meaning:

```
package cats

type Id[A] = A
```

`Id` allows us to abstract over the return types in `UptimeClient`. Implement this now:

- write a trait definition for `UptimeClient` that accepts a type constructor `F[_]` as a parameter;
- extend it with two traits, `RealUptimeClient` and `TestUptimeClient`, that bind `F` to `Future` and `Id` respectively;
- write out the method signature for `getUptime` in each case to verify that it compiles.

See the solution

You should now be able to flesh your definition of `TestUptimeClient` out into a full class based on a `Map[String, Int]` as before.

See the solution

10.2 Abstracting over Monads

Let's turn our attention to `UptimeService`. We need to rewrite it to abstract over the two types of `UptimeClient`. We'll do this in two stages: first we'll rewrite the class and method signatures, then the method bodies. Starting with the method signatures:

- comment out the body of `getTotalUptime` (replace it with `???` to make everything compile);
- add a type parameter `F[_]` to `UptimeService` and pass it on to `UptimeClient`.

See the solution

Now uncomment the body of `getTotalUptime`. You should get a compilation error similar to the following:

```
// <console>:28: error: could not find implicit value for
//           evidence parameter of type cats.Applicative[F]
//           hostnames.traverse(client.getUptime).map(_.sum)
//
```

The problem here is that `traverse` only works on sequences of values that have an `Applicative`. In our original code we were traversing a `List[Future[Int]]`. There is an applicative for `Future` so that was fine. In this version we are traversing a `List[F[Int]]`. We need to prove to the compiler that `F` has an `Applicative`. Do this by adding an implicit constructor parameter to `UptimeService`.

See the solution

Finally, let's turn our attention to our unit tests. Our test code now works as intended without any modification. We create an instance of `TestUptimeClient` and wrap it in an `UptimeService`. This effectively binds `F` to `Id`, allowing the rest of the code to operate synchronously without worrying about monads or applicatives:

```
def testTotalUptime() = {
    val hosts    = Map("host1" -> 10, "host2" -> 6)
    val client   = new TestUptimeClient(hosts)
    val service  = new UptimeService(client)
    val actual   = service.getTotalUptime(hosts.keys.toList)
    val expected = hosts.values.sum
    assert(actual == expected)
}

testTotalUptime()
```

10.3 Summary

This case study provides an example of how Cats can help us abstract over different computational scenarios. We used the `Applicative` type class to abstract over asynchronous and synchronous code. Leaning on a functional abstraction allows us to specify the sequence of computations we want to perform without worrying about the details of the implementation.

Back in Figure 8.1, we showed a “stack” of computational type classes that are meant for exactly this kind of abstraction. Type classes like `Functor`, `Applicative`, `Monad`, and `Traverse` provide abstract implementations of patterns such as mapping, zipping, sequencing, and iteration. The mathematical laws on those types ensure that they work together with a consistent set of semantics.

We used `Applicative` in this case study because it was the least powerful type class that did what we needed. If we had required `flatMap`, we could have swapped out `Applicative` for `Monad`. If we had needed to abstract over different sequence types, we could have used `Traverse`. There are also type classes like `ApplicativeError` and `MonadError` that help model failures as well as successful computations.

Let's move on now to a more complex case study where type classes will help us produce something more interesting: a map-reduce-style framework for parallel processing.

Chapter 11

Case Study: Map-Reduce

In this case study we're going to implement a simple-but-powerful parallel processing framework using Monoids, Functors, and a host of other goodies.

If you have used Hadoop or otherwise worked in "big data" you will have heard of [MapReduce](#), which is a programming model for doing parallel data processing across clusters of machines (aka "nodes"). As the name suggests, the model is built around a *map* phase, which is the same `map` function we know from Scala and the Functor type class, and a *reduce* phase, which we usually call `fold`¹ in Scala.

11.1 Parallelizing `map` and `fold`

Recall the general signature for `map` is to apply a function `A => B` to a `F[A]`, returning a `F[B]`:

`map` transforms each individual element in a sequence independently. We can easily parallelize `map` because there are no dependencies between the transformations applied to different elements (the type signature of the function `A => B` shows us this, assuming we don't use side-effects not reflected in the types).

¹In Hadoop there is also a shuffle phase that we will ignore here.

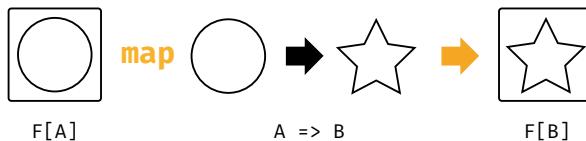

Figure 11.1: Type chart: functor map

Figure 11.2: Type chart: fold

What about `fold`? We can implement this step with an instance of `Foldable`. Not every functor also has an instance of `foldable` but we can implement a map-reduce system on top of any data type that has both of these type classes. Our reduction step becomes a `foldLeft` over the results of the distributed `map`.

By distributing the reduce step we lose control over the order of traversal. Our overall reduction may not be entirely left-to-right—we may reduce left-to-right across several subsequences and then combine the results. To ensure correctness we need a reduction operation that is *associative*:

```
reduce(a1, reduce(a2, a3)) == reduce(reduce(a1, a2), a3)
```

If we have associativity, we can arbitrarily distribute work between our nodes provided the subsequences at every node stay in the same order as the initial dataset.

Our `fold` operation requires us to seed the computation with an element of type `B`. Since `fold` may be split into an arbitrary number of parallel steps, the seed should not affect the result of the computation. This naturally requires the seed to be an *identity* element:

```
reduce(seed, a1) == reduce(a1, seed) == a1
```

In summary, our parallel fold will yield the correct results if:

- we require the reducer function to be associative;
- we seed the computation with the identity of this function.

What does this pattern sound like? That's right, we've come full circle back to `Monoid`, the first type class we discussed in this book. We are not the first to recognise the importance of monoids. The [monoid design pattern for map-reduce jobs](#) is at the core of recent big data systems such as Twitter's `Summingbird`.

In this project we're going to implement a very simple single-machine map-reduce. We'll start by implementing a method called `foldMap` to model the data-flow we need.

11.2 Implementing `foldMap`

We saw `foldMap` briefly back when we covered `Foldable`. It is one of the derived operations that sits on top of `foldLeft` and `foldRight`. However, rather than use `Foldable`, we will re-implement `foldMap` here ourselves as it will provide useful insight into the structure of map-reduce.

Start by writing out the signature of `foldMap`. It should accept the following parameters:

- a sequence of type `Vector[A]`;
- a function of type `A => B`, where there is a `Monoid` for `B`;

You will have to add implicit parameters or context bounds to complete the type signature.

See the solution

Now implement the body of `foldMap`. Use the flow chart in Figure 11.3 as a guide to the steps required:

1. Initial data sequence

2. Map step

3. Fold/reduce step

4. Final result

Figure 11.3: *foldMap* algorithm

1. start with a sequence of items of type A;
2. map over the list to produce a sequence of items of type B;
3. use the Monoid to reduce the items to a single B.

Here's some sample output for reference:

```
import cats.instances.int._ // for Monoid

foldMap(Vector(1, 2, 3))(identity)
// res1: Int = 6

import cats.instances.string._ // for Monoid

// Mapping to a String uses the concatenation monoid:
foldMap(Vector(1, 2, 3))(_.toString + "! ")
// res2: String = "1! 2! 3!"
```

```
// Mapping over a String to produce a String:  
foldMap("Hello world!".toVector)(_.toString.toUpperCase)  
// res3: String = "HELLO WORLD!"
```

See the solution

11.3 Parallelising *foldMap*

Now we have a working single-threaded implementation of `foldMap`, let's look at distributing work to run in parallel. We'll use our single-threaded version of `foldMap` as a building block.

We'll write a multi-CPU implementation that simulates the way we would distribute work in a map-reduce cluster as shown in Figure 11.4:

1. we start with an initial list of all the data we need to process;
2. we divide the data into batches, sending one batch to each CPU;
3. the CPUs run a batch-level map phase in parallel;
4. the CPUs run a batch-level reduce phase in parallel, producing a local result for each batch;
5. we reduce the results for each batch to a single final result.

Scala provides some simple tools to distribute work amongst threads. We could use the [parallel collections library](#) to implement a solution, but let's challenge ourselves by diving a bit deeper and implementing the algorithm ourselves using `Futures`.

11.3.1 *Futures, Thread Pools, and ExecutionContexts*

We already know a fair amount about the monadic nature of `Futures`. Let's take a moment for a quick recap, and to describe how Scala futures are scheduled behind the scenes.

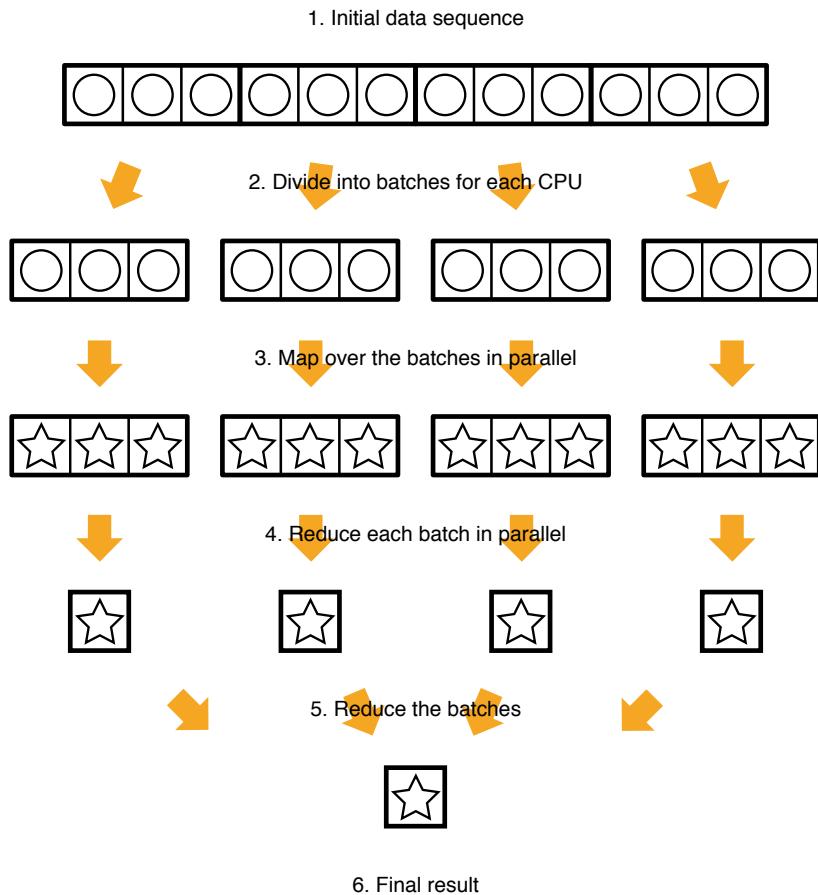

Figure 11.4: *parallelFoldMap* algorithm

Futures run on a thread pool, determined by an implicit `ExecutionContext` parameter. Whenever we create a Future, whether through a call to `Future.apply` or some other combinator, we must have an implicit `ExecutionContext` in scope:

```
import scala.concurrent.Future
import scala.concurrent.ExecutionContext.Implicits.global

val future1 = Future {
  (1 to 100).toList.foldLeft(0)(_ + _)
}
// future1: Future[Int] = Future(Success(5050))

val future2 = Future {
  (100 to 200).toList.foldLeft(0)(_ + _)
}
// future2: Future[Int] = Future(Success(15150))
```

In this example we've imported a `ExecutionContext.Implicits.global`. This default context allocates a thread pool with one thread per CPU in our machine. When we create a Future the `ExecutionContext` schedules it for execution. If there is a free thread in the pool, the Future starts executing immediately. Most modern machines have at least two CPUs, so in our example it is likely that `future1` and `future2` will execute in parallel.

Some combinators create new Futures that schedule work based on the results of other Futures. The `map` and `flatMap` methods, for example, schedule computations that run as soon as their input values are computed and a CPU is available:

```
val future3 = future1.map(_.toString)
// future3: Future[String] = Future(Success(5050))

val future4 = for {
  a <- future1
  b <- future2
} yield a + b
// future4: Future[Int] = Future(Success(20200))
```

As we saw in Section 9.2, we can convert a `List[Future[A]]` to a `Future[List[A]]`:

A]] using Future.sequence:

```
Future.sequence(List(Future(1), Future(2), Future(3)))
// res6: Future[List[Int]] = Future(Success(List(1, 2, 3)))
```

or an instance of Traverse:

```
import cats.instances.future._ // for Applicative
import cats.instances.list._ // for Traverse
import cats.syntax.traverse._ // for sequence

List(Future(1), Future(2), Future(3)).sequence
// res7: Future[List[Int]] = Future(Success(List(1, 2, 3)))
```

An ExecutionContext is required in either case. Finally, we can use Await.result to block on a Future until a result is available:

```
import scala.concurrent._
import scala.concurrent.duration._

Await.result(Future(1), 1.second) // wait for the result
// res8: Int = 1
```

There are also Monad and Monoid implementations for Future available from cats.instances.future:

```
import cats.{Monad, Monoid}
import cats.instances.int._ // for Monoid
import cats.instances.future._ // for Monad and Monoid

Monad[Future].pure(42)

Monoid[Future[Int]].combine(Future(1), Future(2))
```

11.3.2 Dividing Work

Now we've refreshed our memory of Futures, let's look at how we can divide work into batches. We can query the number of available CPUs on our machine using an API call from the Java standard library:

```
Runtime.getRuntime.availableProcessors  
// res11: Int = 2
```

We can partition a sequence (actually anything that implements `Vector`) using the `grouped` method. We'll use this to split off batches of work for each CPU:

```
(1 to 10).toList.grouped(3).toList  
// res12: List[List[Int]] = List(  
//   List(1, 2, 3),  
//   List(4, 5, 6),  
//   List(7, 8, 9),  
//   List(10)  
// )
```

11.3.3 Implementing `parallelFoldMap`

Implement a parallel version of `foldMap` called `parallelFoldMap`. Here is the type signature:

```
def parallelFoldMap[A, B : Monoid]  
  (values: Vector[A])  
  (func: A => B): Future[B] = ???
```

Use the techniques described above to split the work into batches, one batch per CPU. Process each batch in a parallel thread. Refer back to Figure 11.4 if you need to review the overall algorithm.

For bonus points, process the batches for each CPU using your implementation of `foldMap` from above.

See the solution

11.3.4 `parallelFoldMap` with more Cats

Although we implemented `foldMap` ourselves above, the method is also available as part of the `Foldable` type class we discussed in Section 9.1.

Reimplement `parallelFoldMap` using Cats' `Foldable` and `Traversable` type classes.

See the solution

11.4 Summary

In this case study we implemented a system that imitates map-reduce as performed on a cluster. Our algorithm followed three steps:

1. batch the data and send one batch to each “node”;
2. perform a local map-reduce on each batch;
3. combine the results using monoid addition.

Our toy system emulates the batching behaviour of real-world map-reduce systems such as Hadoop. However, in reality we are running all of our work on a single machine where communication between nodes is negligible. We don't actually need to batch data to gain efficient parallel processing of a list. We can simply map using a `Functor` and reduce using a `Monoid`.

Regardless of the batching strategy, mapping and reducing with `Monoids` is a powerful and general framework that isn't limited to simple tasks like addition and string concatenation. Most of the tasks data scientists perform in their day-to-day analyses can be cast as monoids. There are monoids for all the following:

- approximate sets such as the Bloom filter;
- set cardinality estimators, such as the HyperLogLog algorithm;
- vectors and vector operations like stochastic gradient descent;
- quantile estimators such as the t-digest

to name but a few.

Chapter 12

Case Study: Data Validation

In this case study we will build a library for validation. What do we mean by validation? Almost all programs must check their input meets certain criteria. Usernames must not be blank, email addresses must be valid, and so on. This type of validation often occurs in web forms, but it could be performed on configuration files, on web service responses, and any other case where we have to deal with data that we can't guarantee is correct. Authentication, for example, is just a specialised form of validation.

We want to build a library that performs these checks. What design goals should we have? For inspiration, let's look at some examples of the types of checks we want to perform:

- A user must be over 18 years old or must have parental consent.
- A `String` ID must be parsable as a `Int` and the `Int` must correspond to a valid record ID.
- A bid in an auction must apply to one or more items and have a positive value.
- A username must contain at least four characters and all characters must be alphanumeric.

- An email address must contain a single @ sign. Split the string at the @. The string to the left must not be empty. The string to the right must be at least three characters long and contain a dot.

With these examples in mind we can state some goals:

- We should be able to associate meaningful messages with each validation failure, so the user knows why their data is not valid.
- We should be able to combine small checks into larger ones. Taking the username example above, we should be able to express this by combining a check of length and a check for alphanumeric values.
- We should be able to transform data while we are checking it. There is an example above requiring we parse data, changing its type from String to Int.
- Finally, we should be able to accumulate all the failures in one go, so the user can correct all the issues before resubmitting.

These goals assume we're checking a single piece of data. We will also need to combine checks across multiple pieces of data. For a login form, for example, we'll need to combine the check results for the username and the password. This will turn out to be quite a small component of the library, so the majority of our time will focus on checking a single data item.

12.1 Sketching the Library Structure

Let's start at the bottom, checking individual pieces of data. Before we start coding let's try to develop a feel for what we'll be building. We can use a graphical notation to help us. We'll go through our goals one by one.

Providing error messages

Our first goal requires us to associate useful error messages with a check failure. The output of a check could be either the value being checked, if it

 $F[A]$

Figure 12.1: A validation result

 $A \Rightarrow F[A]$

Figure 12.2: A validation check

passed the check, or some kind of error message. We can abstractly represent this as a value in a context, where the context is the possibility of an error message as shown in Figure 12.1.

A check itself is therefore a function that transforms a value into a value in a context as shown in Figure 12.2.

Combine checks

How do we combine smaller checks into larger ones? Is this an applicative or semigroupal as shown in Figure 12.3?

Not really. With applicative combination, both checks are applied to the same value and result in a tuple with the value repeated. What we want feels more like a monoid as shown in Figure 12.4. We can define a sensible identity—a check that always passes—and two binary combination operators—*and* and *or*:

We'll probably be using *and* and *or* about equally often with our validation

 $A \Rightarrow F[A]$ $A \Rightarrow F[A]$ $A \Rightarrow F[(A, A)]$

Figure 12.3: Applicative combination of checks

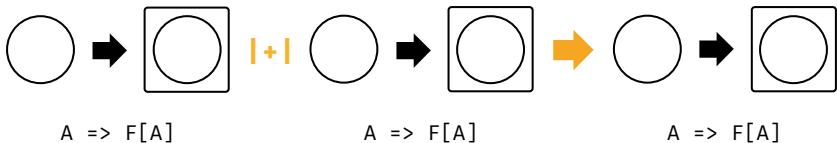

Figure 12.4: Monoid combination of checks

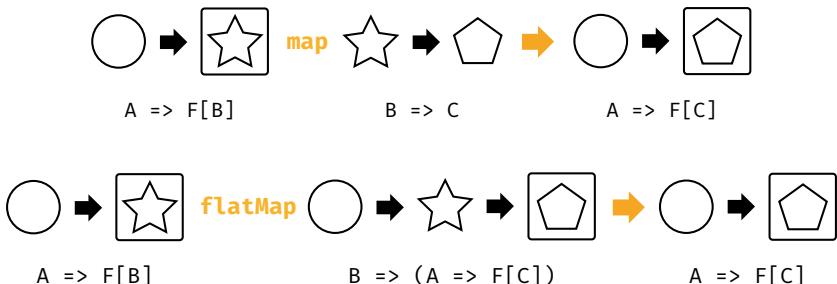

Figure 12.5: Monadic combination of checks

library and it will be annoying to continuously switch between two monoids for combining rules. We consequently won't actually use the monoid API: we'll use two separate methods, and and or, instead.

Accumulating errors as we check

Monoids also feel like a good mechanism for accumulating error messages. If we store messages as a List or NonEmptyList, we can even use a pre-existing monoid from inside Cats.

Transforming data as we check it

In addition to checking data, we also have the goal of transforming it. This seems like it should be a map or a flatMap depending on whether the transform can fail or not, so it seems we also want checks to be a monad as shown in Figure 12.5.

We've now broken down our library into familiar abstractions and are in a good position to begin development.

12.2 The Check Datatype

Our design revolves around a `Check`, which we said was a function from a value to a value in a context. As soon as you see this description you should think of something like

```
type Check[A] = A => Either[String, A]
```

Here we've represented the error message as a `String`. This is probably not the best representation. We may want to accumulate messages in a `List`, for example, or even use a different representation that allows for internationalization or standard error codes.

We could attempt to build some kind of `ErrorMessage` type that holds all the information we can think of. However, we can't predict the user's requirements. Instead let's let the user specify what they want. We can do this by adding a second type parameter to `Check`:

```
type Check[E, A] = A => Either[E, A]
```

We will probably want to add custom methods to `Check` so let's declare it as a trait instead of a type alias:

```
trait Check[E, A] {  
    def apply(value: A): Either[E, A]  
  
    // other methods...  
}
```

As we said in [Essential Scala](#), there are two functional programming patterns that we should consider when defining a trait:

- we can make it a typeclass, or;
- we can make it an algebraic data type (and hence seal it).

Type classes allow us to unify disparate data types with a common interface. This doesn't seem like what we're trying to do here. That leaves us with an

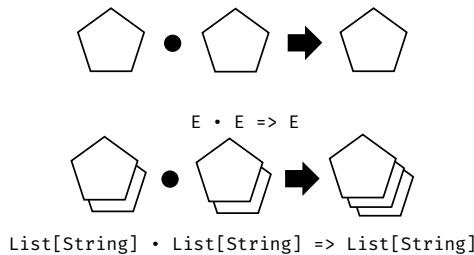

Figure 12.6: Combining error messages

algebraic data type. Let's keep that thought in mind as we explore the design a bit further.

12.3 Basic Combinators

Let's add some combinator methods to `Check`, starting with `and`. This method combines two checks into one, succeeding only if both checks succeed. Think about implementing this method now. You should hit some problems. Read on when you do!

```
trait Check[E, A] {
  def and(that: Check[E, A]): Check[E, A] =
    ???

  // other methods...
}
```

The problem is: what do you do when *both* checks fail? The correct thing to do is to return both errors, but we don't currently have any way to combine `E`s. We need a *type class* that abstracts over the concept of "accumulating" errors as shown in Figure 12.6. What type class do we know that looks like this? What method or operator should we use to implement the `?` operation?

See the solution

There is another semantic issue that will come up quite quickly: should and short-circuit if the first check fails. What do you think the most useful behaviour is?

See the solution

Use this knowledge to implement and. Make sure you end up with the behaviour you expect!

See the solution

Strictly speaking, Either[E, A] is the wrong abstraction for the output of our check. Why is this the case? What other data type could we use instead? Switch your implementation over to this new data type.

See the solution

Our implementation is looking pretty good now. Implement an or combinator to complement and.

See the solution

With and and or we can implement many of checks we'll want in practice. However, we still have a few more methods to add. We'll turn to map and related methods next.

12.4 Transforming Data

One of our requirements is the ability to transform data. This allows us to support additional scenarios like parsing input. In this section we'll extend our check library with this additional functionality.

The obvious starting point is map. When we try to implement this, we immediately run into a wall. Our current definition of Check requires the input and output types to be the same:

```
type Check[E, A] = A => Either[E, A]
```

When we map over a check, what type do we assign to the result? It can't be A and it can't be B. We are at an impasse:

```
def map(check: Check[E, A])(func: A => B): Check[E, ???]
```

To implement `map` we need to change the definition of `Check`. Specifically, we need to a new type variable to separate the input type from the output:

```
type Check[E, A, B] = A => Either[E, B]
```

Checks can now represent operations like parsing a String as an Int:

```
val parseInt: Check[List[String], String, Int] =
  // etc...
```

However, splitting our input and output types raises another issue. Up until now we have operated under the assumption that a `Check` always returns its input when successful. We used this in `and` and `or` to ignore the output of the left and right rules and simply return the original input on success:

```
(this(a), that(a)) match {
  case And(left, right) =>
    (left(a), right(a))
      .mapN((result1, result2) => Right(a))

  // etc...
}
```

In our new formulation we can't return `Right(a)` because its type is `Either[E, A]` not `Either[E, B]`. We're forced to make an arbitrary choice between returning `Right(result1)` and `Right(result2)`. The same is true of the `or` method. From this we can derive two things:

- we should strive to make the laws we adhere to explicit; and
- the code is telling us we have the wrong abstraction in `Check`.

12.4.1 Predicates

We can make progress by pulling apart the concept of a *predicate*, which can be combined using logical operations such as *and* and *or*, and the concept of a *check*, which can transform data.

What we have called Check so far we will call Predicate. For Predicate we can state the following *identity law* encoding the notion that a predicate always returns its input if it succeeds:

For a predicate p of type $\text{Predicate}[E, A]$ and elements a_1 and a_2 of type A , if $p(a_1) == \text{Success}(a_2)$ then $a_1 == a_2$.

Making this change gives us the following code:

```
import cats.Semigroup
import cats.data.Validated
import cats.syntax.semigroup._ // for |+
import cats.syntax.apply._    // for mapN
import cats.data.Validated._ // for Valid and Invalid

sealed trait Predicate[E, A] {
  def and(that: Predicate[E, A]): Predicate[E, A] =
    And(this, that)

  def or(that: Predicate[E, A]): Predicate[E, A] =
    Or(this, that)

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, A] =
    this match {
      case Pure(func) =>
        func(a)

      case And(left, right) =>
        (left(a), right(a)).mapN(_ _, _) => a

      case Or(left, right) =>
        left(a) match {
          case Valid(_)  => Valid(a)
          case Invalid(e1) =>
            right(a) match {
              case Valid(_)  => Valid(a)
              case Invalid(e2) => Invalid(e1 |+| e2)
            }
        }
    }
}
```

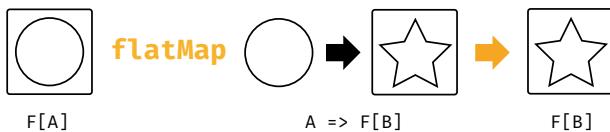

Figure 12.7: Type chart for flatMap

```

final case class And[E, A](
  left: Predicate[E, A],
  right: Predicate[E, A]) extends Predicate[E, A]

final case class Or[E, A](
  left: Predicate[E, A],
  right: Predicate[E, A]) extends Predicate[E, A]

final case class Pure[E, A](
  func: A => Validated[E, A]) extends Predicate[E, A]

```

12.4.2 Checks

We'll use Check to represent a structure we build from a Predicate that also allows transformation of its input. Implement Check with the following interface:

```

sealed trait Check[E, A, B] {
  def apply(a: A): Validated[E, B] =
    ???

  def map[C](func: B => C): Check[E, A, C] =
    ???
}

```

See the solution

What about flatMap? The semantics are a bit unclear here. The method is simple enough to declare but it's not so obvious what it means or how we should implement apply. The general shape of flatMap is shown in Figure 12.7.

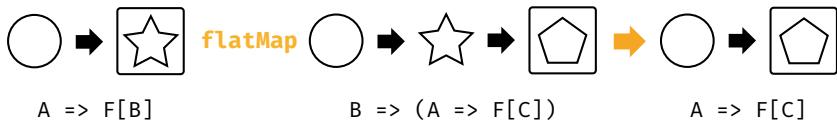

Figure 12.8: Type chart for flatMap applied to Check

How do we relate F in the figure to `Check` in our code? `Check` has *three* type variables while F only has one.

To unify the types we need to fix two of the type parameters. The idiomatic choices are the error type E and the input type A . This gives us the relationships shown in Figure 12.8. In other words, the semantics of applying a `flatMap` are:

- given an input of type A , convert to $F[B]$;
- use the output of type B to choose a `Check[E, A, C]`;
- return to the *original* input of type A and apply it to the chosen check to generate the final result of type $F[C]$.

This is quite an odd method. We can implement it, but it is hard to find a use for it. Go ahead and implement `flatMap` for `Check`, and then we'll see a more generally useful method.

See the solution

We can write a more useful combinator that chains together two `Checks`. The output of the first check is connected to the input of the second. This is analogous to function composition using `andThen`:

```
val f: A => B = ???  
val g: B => C = ???  
val h: A => C = f andThen g
```

A `Check` is basically a function $A \Rightarrow \text{Validated}[E, B]$ so we can define an analogous `andThen` method:

```
trait Check[E, A, B] {  
    def andThen[C](that: Check[E, B, C]): Check[E, A, C]  
}
```

Implement `andThen` now!

See the solution

12.4.3 Recap

We now have two algebraic data types, `Predicate` and `Check`, and a host of combinators with their associated case class implementations. Look at the following solution for a complete definition of each ADT.

See the solution

We have a complete implementation of `Check` and `Predicate` that do most of what we originally set out to do. However, we are not finished yet. You have probably recognised structure in `Predicate` and `Check` that we can abstract over: `Predicate` has a monoid and `Check` has a monad. Furthermore, in implementing `Check` you might have felt the implementation doesn't do much—all we do is call through to underlying methods on `Predicate` and `Validated`.

There are a lot of ways this library could be cleaned up. However, let's implement some examples to prove to ourselves that our library really does work, and then we'll turn to improving it.

Implement checks for some of the examples given in the introduction:

- A username must contain at least four characters and consist entirely of alphanumeric characters
- An email address must contain an @ sign. Split the string at the @. The string to the left must not be empty. The string to the right must be at least three characters long and contain a dot.

You might find the following predicates useful:

```

import cats.data.{NonEmptyList, Validated}

type Errors = NonEmptyList[String]

def error(s: String): NonEmptyList[String] =
  NonEmptyList(s, Nil)

def longerThan(n: Int): Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must be longer than $n characters"),
    str => str.size > n)

val alphanumeric: Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must be all alphanumeric characters"),
    str => str.forall(_.isLetterOrDigit))

def contains(char: Char): Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must contain the character $char"),
    str => str.contains(char))

def containsOnce(char: Char): Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must contain the character $char only once"),
    str => str.filter(c => c == char).size == 1)

```

See the solution

12.5 Kleislis

We'll finish off this case study by cleaning up the implementation of `check`. A justifiable criticism of our approach is that we've written a lot of code to do very little. A `Predicate` is essentially a function `A => Validated[E, A]`, and a `Check` is basically a wrapper that lets us compose these functions.

We can abstract `A => Validated[E, A]` to `A => F[B]`, which you'll recognise as the type of function you pass to the `flatMap` method on a monad. Imagine we have the following sequence of operations:

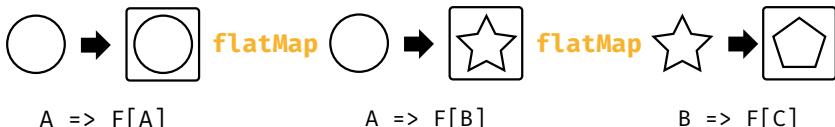

Figure 12.9: Sequencing monadic transforms

- We lift some value into a monad (by using `pure`, for example). This is a function with type $A \Rightarrow F[A]$.
- We then sequence some transformations on the monad using `flatMap`.

We can illustrate this as shown in Figure 12.9. We can also write out this example using the monad API as follows:

```
val aToB: A => F[B] = ???
val bToC: B => F[C] = ???

def example[A, C](a: A): F[C] =
  aToB(a).flatMap(bToC)
```

Recall that `Check` is, in the abstract, allowing us to compose functions of type $A \Rightarrow F[B]$. We can write the above in terms of `andThen` as:

```
val aToC = aToB andThen bToC
```

The result is a (wrapped) function `aToC` of type $A \Rightarrow F[C]$ that we can subsequently apply to a value of type A .

We have achieved the same thing as the `example` method without having to reference an argument of type A . The `andThen` method on `Check` is analogous to function composition, but is composing function $A \Rightarrow F[B]$ instead of $A \Rightarrow B$.

The abstract concept of composing functions of type $A \Rightarrow F[B]$ has a name: a *Kleisli*.

Cats contains a data type `cats.data.Kleisli` that wraps a function just as `Check` does. `Kleisli` has all the methods of `Check` plus some additional ones. If `Kleisli` seems familiar to you, then congratulations. You've seen through its

disguise and recognised it as another concept from earlier in the book: Kleisli is just another name for ReaderT.

Here is a simple example using Kleisli to transform an integer into a list of integers through three steps:

```
import cats.data.Kleisli
import cats.instances.list._ // for Monad
```

These steps each transform an input Int into an output of type List[Int]:

```
val step1: Kleisli[List, Int, Int] =
  Kleisli(x => List(x + 1, x - 1))

val step2: Kleisli[List, Int, Int] =
  Kleisli(x => List(x, -x))

val step3: Kleisli[List, Int, Int] =
  Kleisli(x => List(x * 2, x / 2))
```

We can combine the steps into a single pipeline that combines the underlying Lists using flatMap:

```
val pipeline = step1 andThen step2 andThen step3
```

The result is a function that consumes a single Int and returns eight outputs, each produced by a different combination of transformations from step1, step2, and step3:

```
pipeline.run(20)
// res0: List[Int] = List(42, 10, -42, -10, 38, 9, -38, -9)
```

The only notable difference between Kleisli and Check in terms of API is that Kleisli renames our apply method to run.

Let's replace Check with Kleisli in our validation examples. To do so we need to make a few changes to Predicate. We must be able to convert a Predicate to a function, as Kleisli only works with functions. Somewhat more subtly,

when we convert a `Predicate` to a function, it should have type `A => Either[E, A]` rather than `A => Validated[E, A]` because `Kleisli` relies on the wrapped function returning a monad.

Add a method to `Predicate` called `run` that returns a function of the correct type. Leave the rest of the code in `Predicate` the same.

See the solution

Now rewrite our username and email validation example in terms of `Kleisli` and `Predicate`. Here are few tips in case you get stuck:

First, remember that the `run` method on `Predicate` takes an implicit parameter. If you call `aPredicate.run(a)` it will try to pass the implicit parameter explicitly. If you want to create a function from a `Predicate` and immediately apply that function, use `aPredicate.run.apply(a)`

Second, type inference can be tricky in this exercise. We found that the following definitions helped us to write code with fewer type declarations.

```
type Result[A] = Either[Errors, A]

type Check[A, B] = Kleisli[Result, A, B]

// Create a check from a function:
def check[A, B](func: A => Result[B]): Check[A, B] =
  Kleisli(func)

// Create a check from a Predicate:
def checkPred[A](pred: Predicate[Errors, A]): Check[A, A] =
  Kleisli[Result, A, A](pred.run)
```

See the solution

We have now written our code entirely in terms of `Kleisli` and `Predicate`, completely removing `Check`. This is a good first step to simplifying our library. There's still plenty more to do, but we have a sophisticated building block from Cats to work with. We'll leave further improvements up to the reader.

12.6 Summary

This case study has been an exercise in removing rather than building abstractions. We started with a fairly complex check type. Once we realised we were conflating two concepts, we separated out `Predicate` leaving us with something that could be implemented with `Kleisli`.

We made several design choices above that reasonable developers may disagree with. Should the method that converts a `Predicate` to a function really be called `run` instead of, say, `toFunction`? Should `Predicate` be a subtype of `Function` to begin with? Many functional programmers prefer to avoid subtyping because it plays poorly with implicit resolution and type inference, but there could be an argument to use it here. As always the best decisions depend on the context in which the library will be used.

Chapter 13

Case Study: CRDTs

In this case study we will explore *Commutative Replicated Data Types* (CRDTs), a family of data structures that can be used to reconcile eventually consistent data.

We'll start by describing the utility and difficulty of eventually consistent systems, then show how we can use monoids and their extensions to solve the issues that arise. Finally, we will model the solutions in Scala.

Our goal here is to focus on the implementation in Scala of a particular type of CRDT. We're not aiming at a comprehensive survey of all CRDTs. CRDTs are a fast-moving field and we advise you to read the literature to learn about more.

13.1 Eventual Consistency

As soon as a system scales beyond a single machine we have to make a fundamental choice about how we manage data.

One approach is to build a system that is *consistent*, meaning that all machines have the same view of data. For example, if a user changes their password then all machines that store a copy of that password must accept the change before we consider the operation to have completed successfully.

Consistent systems are easy to work with but they have their disadvantages. They tend to have high latency because a single change can result in many messages being sent between machines. They also tend to have relatively low uptime because outages can cut communications between machines creating a *network partition*. When there is a network partition, a consistent system may refuse further updates to prevent inconsistencies across machines.

An alternative approach is an *eventually consistent* system. This means that at any particular point in time machines are allowed to have differing views of data. However, if all machines can communicate and there are no further updates they will eventually all have the same view of data.

Eventually consistent systems require less communication between machines so latency can be lower. A partitioned machine can still accept updates and reconcile its changes when the network is fixed, so systems can also have better uptime.

The big question is: how do we do this reconciliation between machines? CRDTs provide one approach to the problem.

13.2 The GCounter

Let's look at one particular CRDT implementation. Then we'll attempt to generalise properties to see if we can find a general pattern.

The data structure we will look at is called a *GCounter*. It is a distributed *increment-only* counter that can be used, for example, to count the number of visitors to a web site where requests are served by many web servers.

13.2.1 Simple Counters

To see why a straightforward counter won't work, imagine we have two servers storing a simple count of visitors. Let's call the machines A and B. Each machine is storing an integer counter and the counters all start at zero as shown in Figure 13.1.

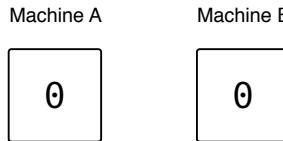

Figure 13.1: Simple counters: initial state

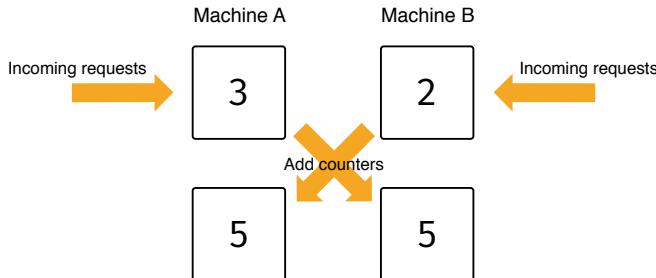

Figure 13.2: Simple counters: first round of requests and reconciliation

Now imagine we receive some web traffic. Our load balancer distributes five incoming requests to A and B, A serving three visitors and B two. The machines have inconsistent views of the system state that they need to *reconcile* to achieve consistency. One reconciliation strategy with simple counters is to exchange counts and add them as shown in Figure 13.2.

So far so good, but things will start to fall apart shortly. Suppose A serves a single visitor, which means we've seen six visitors in total. The machines attempt to reconcile state again using addition leading to the answer shown in Figure 13.3.

This is clearly wrong! The problem is that simple counters don't give us enough information about the history of interactions between the machines. Fortunately we don't need to store the *complete* history to get the correct answer—just a summary of it. Let's look at how the GCounter solves this problem.

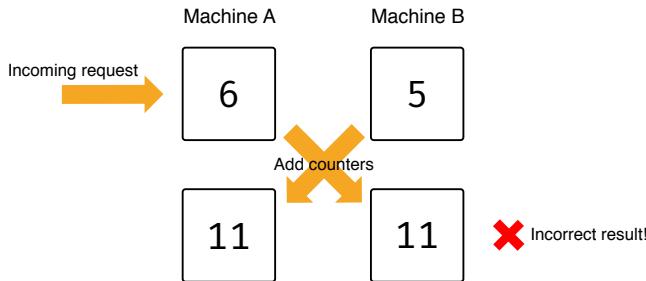

Figure 13.3: Simple counters: second round of requests and (incorrect) reconciliation

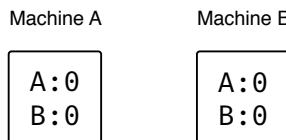

Figure 13.4: GCounter: initial state

13.2.2 GCounters

The first clever idea in the GCounter is to have each machine storing a *separate* counter for every machine it knows about (including itself). In the previous example we had two machines, A and B. In this situation both machines would store a counter for A and a counter for B as shown in Figure 13.4.

The rule with GCounters is that a given machine is only allowed to increment its own counter. If A serves three visitors and B serves two visitors the counters look as shown in Figure 13.5.

When two machines reconcile their counters the rule is to take the largest value stored for each machine. In our example, the result of the first merge will be as shown in Figure 13.6.

Subsequent incoming web requests are handled using the increment-own-counter rule and subsequent merges are handled using the take-maximum-value rule, producing the same correct values for each machine as shown in

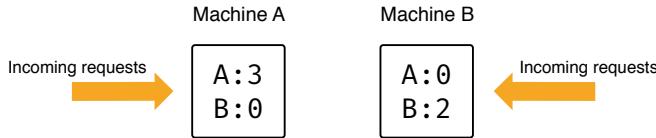

Figure 13.5: GCounter: first round of web requests

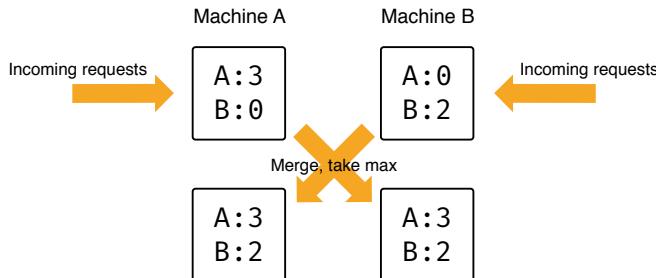

Figure 13.6: GCounter: first reconciliation

Figure 13.7.

GCounters allow each machine to keep an accurate account of the state of the whole system without storing the complete history of interactions. If a machine wants to calculate the total traffic for the whole web site, it sums up all the per-machine counters. The result is accurate or near-accurate depending on how recently we performed a reconciliation. Eventually, regardless of network outages, the system will always converge on a consistent state.

13.2.3 Exercise: GCounter Implementation

We can implement a GCounter with the following interface, where we represent machine IDs as strings.

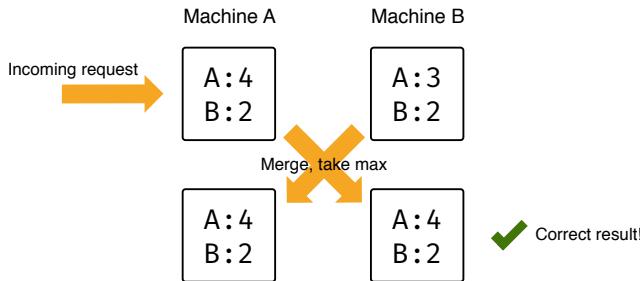

Figure 13.7: GCounter: second reconciliation

```
final case class GCounter(counters: Map[String, Int]) {
  def increment(machine: String, amount: Int) =
    ???

  def merge(that: GCounter): GCounter =
    ???

  def total: Int =
    ???
}
```

Finish the implementation!

See the solution

13.3 Generalisation

We've now created a distributed, eventually consistent, increment-only counter. This is a useful achievement but we don't want to stop here. In this section we will attempt to abstract the operations in the GCounter so it will work with more data types than just natural numbers.

The GCounter uses the following operations on natural numbers:

- addition (in `increment` and `total`);

- maximum (in `merge`);
- and the identity element 0 (in `increment` and `merge`).

You can probably guess that there's a monoid in here somewhere, but let's look in more detail at the properties we're relying on.

As a refresher, in Chapter 4 we saw that monoids must satisfy two laws. The binary operation `+` must be associative:

$$(a + b) + c == a + (b + c)$$

and the empty element must be an identity:

$$0 + a == a + 0 == a$$

We need an identity in `increment` to initialise the counter. We also rely on associativity to ensure the specific sequence of merges gives the correct value.

In total we implicitly rely on associativity and commutativity to ensure we get the correct value no matter what arbitrary order we choose to sum the per-machine counters. We also implicitly assume an identity, which allows us to skip machines for which we do not store a counter.

The properties of `merge` are a bit more interesting. We rely on commutativity to ensure that machine A merging with machine B yields the same result as machine B merging with machine A. We need associativity to ensure we obtain the correct result when three or more machines are merging data. We need an identity element to initialise empty counters. Finally, we need an additional property, called *idempotency*, to ensure that if two machines hold the same data in a per-machine counter, merging data will not lead to an incorrect result. Idempotent operations are ones that return the same result again and again if they are executed multiple times. Formally, a binary operation `max` is idempotent if the following relationship holds:

$$a \max a = a$$

Written more compactly, we have:

Method	Identity	Commutative	Associative	Idempotent
increment	Y	N	Y	N
merge	Y	Y	Y	Y
total	Y	Y	Y	N

From this we can see that

- `increment` requires a monoid;
- `total` requires a commutative monoid; and
- `merge` required an idempotent commutative monoid, also called a *bounded semilattice*.

Since `increment` and `get` both use the same binary operation (addition) it's usual to require the same commutative monoid for both.

This investigation demonstrates the powers of thinking about properties or laws of abstractions. Now we have identified these properties we can substitute the natural numbers used in our `GCounter` with any data type with operations satisfying these properties. A simple example is a set, with the binary operation being union and the identity element the empty set. With this simple substitution of `Int` for `Set[A]` we can create a `GSet` type.

13.3.1 Implementation

Let's implement this generalisation in code. Remember `increment` and `total` require a commutative monoid and `merge` requires a bounded semilattice (or idempotent commutative monoid).

Cats provides a type class for both `Monoid` and `CommutativeMonoid`, but doesn't provide one for bounded semilattice¹. That's why we're going to implement our own `BoundedSemiLattice` type class.

¹A closely related library called [Spire](#) already provides that abstractions.

```
import cats.kernel.CommutativeMonoid

trait BoundedSemiLattice[A] extends CommutativeMonoid[A] {
    def combine(a1: A, a2: A): A
    def empty: A
}
```

In the implementation above, `BoundedSemiLattice[A]` extends `CommutativeMonoid[A]` because a bounded semilattice is a commutative monoid (a commutative idempotent one, to be exact).

13.3.2 Exercise: BoundedSemiLattice Instances

Implement `BoundedSemiLattice` type class instances for `Ints` and for `Sets`. The instance for `Int` will technically only hold for non-negative numbers, but you don't need to model non-negativity explicitly in the types.

See the solution

13.3.3 Exercise: Generic GCounter

Using `CommutativeMonoid` and `BoundedSemiLattice`, generalise `GCounter`.

When you implement this, look for opportunities to use methods and syntax on `Monoid` to simplify your implementation. This is a good example of how type class abstractions work at multiple levels in our code. We're using monoids to design a large component—our CRDTs—but they are also useful in the small, simplifying our code and making it shorter and clearer.

See the solution

13.4 Abstracting GCounter to a Type Class

We've created a generic `GCounter` that works with any value that has instances of `BoundedSemiLattice` and `CommutativeMonoid`. However we're still tied to a particular representation of the map from machine IDs to values.

There is no need to have this restriction, and indeed it can be useful to abstract away from it. There are many key-value stores that we want to work with, from a simple Map to a relational database.

If we define a GCounter type class we can abstract over different concrete implementations. This allows us to, for example, seamlessly substitute an in-memory store for a persistent store when we want to change performance and durability tradeoffs.

There are a number of ways we can implement this. One approach is to define a GCounter type class with dependencies on CommutativeMonoid and BoundedSemiLattice. We define this as a type class that takes a type constructor with two type parameters represent the key and value types of the map abstraction.

```
trait GCounter[F[_,_],K, V] {
    def increment(f: F[K, V])(k: K, v: V)
        (implicit m: CommutativeMonoid[V]): F[K, V]

    def merge(f1: F[K, V], f2: F[K, V])
        (implicit b: BoundedSemiLattice[V]): F[K, V]

    def total(f: F[K, V])
        (implicit m: CommutativeMonoid[V]): V
}

object GCounter {
    def apply[F[_,_], K, V]
        (implicit counter: GCounter[F, K, V]) =
        counter
}
```

Try defining an instance of this type class for Map. You should be able to reuse your code from the case class version of GCounter with some minor modifications.

See the solution

You should be able to use your instance as follows:

```
import cats.instances.int._ // for Monoid

val g1 = Map("a" -> 7, "b" -> 3)
val g2 = Map("a" -> 2, "b" -> 5)

val counter = GCounter[Map, String, Int]

val merged = counter.merge(g1, g2)
// merged: Map[String, Int] = Map("a" -> 7, "b" -> 5)
val total  = counter.total(merged)
// total: Int = 12
```

The implementation strategy for the type class instance is a bit unsatisfying. Although the structure of the implementation will be the same for most instances we define, we won't get any code reuse.

13.5 Abstracting a Key Value Store

One solution is to capture the idea of a key-value store within a type class, and then generate `GCounter` instances for any type that has a `KeyValueStore` instance. Here's the code for such a type class:

```
trait KeyValueStore[F[_,_]] {
  def put[K, V](f: F[K, V])(k: K, v: V): F[K, V]

  def get[K, V](f: F[K, V])(k: K): Option[V]

  def getOrElse[K, V](f: F[K, V])(k: K, default: V): V =
    get(f)(k).getOrElse(default)

  def values[K, V](f: F[K, V]): List[V]
}
```

Implement your own instance for `Map`.

See the solution

With our type class in place we can implement syntax to enhance data types for which we have instances:

```
implicit class KvsOps[F[_,_], K, V](f: F[K, V]) {
    def put(key: K, value: V)
        (implicit kvs: KeyValueStore[F]): F[K, V] =
            kvs.put(f)(key, value)

    def get(key: K)(implicit kvs: KeyValueStore[F]): Option[V] =
        kvs.get(f)(key)

    def getOrElse(key: K, default: V)
        (implicit kvs: KeyValueStore[F]): V =
            kvs.getOrElse(f)(key, default)

    def values(implicit kvs: KeyValueStore[F]): List[V] =
        kvs.values(f)
}
```

Now we can generate GCounter instances for any data type that has instances of KeyValueStore and CommutativeMonoid using an `implicit def`:

```
implicit def gcounterInstance[F[_,_], K, V]
    (implicit kvs: KeyValueStore[F], km: CommutativeMonoid[F[K, V]]):
    GCounter[F, K, V] =
new GCounter[F, K, V] {
    def increment(f: F[K, V])(key: K, value: V)
        (implicit m: CommutativeMonoid[V]): F[K, V] = {
            val total = f.getOrElse(key, m.empty) |+| value
            f.put(key, total)
    }

    def merge(f1: F[K, V], f2: F[K, V])
        (implicit b: BoundedSemiLattice[V]): F[K, V] =
            f1 |+| f2

    def total(f: F[K, V])(implicit m: CommutativeMonoid[V]): V =
        f.values.combineAll
}
```

The complete code for this case study is quite long, but most of it is boilerplate setting up syntax for operations on the type class. We can cut down on this using compiler plugins such as [Simulacrum](#) and [Kind Projector](#).

13.6 Summary

In this case study we've seen how we can use type classes to model a simple CRDT, the GCounter, in Scala. Our implementation gives us a lot of flexibility and code reuse: we aren't tied to the data type we "count", nor to the data type that maps machine IDs to counters.

The focus in this case study has been on using the tools that Scala provides, not on exploring CRDTs. There are many other CRDTs, some of which operate in a similar manner to the GCounter, and some of which have very different implementations. A [fairly recent survey](#) gives a good overview of many of the basic CRDTs. However this is an active area of research and we encourage you to read the recent publications in the field if CRDTs and eventually consistency interest you.

Part III

Solutions to Exercises

Appendix A

Solutions for: Algebraic Data Types

A.1 Iterate

```
object MyList {  
    def unfold[A, B](seed: A)(stop: A => Boolean, f: A => B, next: A =>  
        A): MyList[B] =  
        if stop(seed) then MyList.Empty()  
        else MyList.Pair(f(seed), unfold(next(seed))(stop, f, next))  
  
    def fill[A](n: Int)(elem: => A): MyList[A] =  
        unfold(n)(_ == 0)(_ => elem, _ - 1)  
  
    def iterate[A](start: A, len: Int)(f: A => A): MyList[A] =  
        unfold((len, start)){  
            (len, _) => len == 0,  
            (_, start) => start,  
            (len, start) => (len - 1, f(start))  
        }  
}
```

We should check that this works.

```
List.iterate(0, 5)(x => x - 1)
// res11: List[Int] = List(0, -1, -2, -3, -4)
MyList.iterate(0, 5)(x => x - 1)
// res12: MyList[Int] = MyList(0, -1, -2, -3, -4)
```

[Return to the exercise](#)

A.2 Map

```
def map[B](f: A => B): MyList[B] =
  MyList.unfold(this)(
    _.isEmpty,
    pair => f(pair.head),
    pair => pair.tail
  )

List.iterate(0, 5)(x => x + 1).map(x => x * 2)
// res13: List[Int] = List(0, 2, 4, 6, 8)
MyList.iterate(0, 5)(x => x + 1).map(x => x * 2)
// res14: MyList[Int] = MyList(0, 2, 4, 6, 8)
```

[Return to the exercise](#)

A.3 Identities

It's `Unit`, because adding `Unit` to any product doesn't add any more information. So, `Int` contains exactly as much information as `Int × Unit` (written as the tuple `(Int, Unit)` in Scala).

[Return to the exercise](#)

A.4 Identities Part 2

It's `Nothing`, following the same reasoning as products: a case of `Nothing` adds no further information (and we cannot even create a value with this type.)

[Return to the exercise](#)

Appendix B

Solutions for: Type Classes

B.1 Printable Library

These steps define the three main components of our type class. First we define `Printable`—the *type class* itself:

```
trait Printable[A] {  
    def format(value: A): String  
}
```

Then we define some default *instances* of `Printable` and package them in `PrintableInstances`:

```
object PrintableInstances {  
    implicit val stringPrintable: Printable[String] = new Printable[  
        String] {  
        def format(input: String) = input  
    }  
  
    implicit val intPrintable: Printable[Int] = new Printable[Int] {  
        def format(input: Int) = input.toString  
    }  
}
```

Finally we define an *interface* object, `Printable`:

```
object Printable {
  def format[A](input: A)(implicit p: Printable[A]): String =
    p.format(input)

  def print[A](input: A)(implicit p: Printable[A]): Unit =
    println(p.format(input))
}
```

[Return to the exercise](#)

B.2 Printable Library Part 2

This is a standard use of the type class pattern. First we define a set of custom data types for our application:

```
final case class Cat(name: String, age: Int, color: String)
```

Then we define type class instances for the types we care about. These either go into the companion object of `Cat` or a separate object to act as a namespace:

```
import PrintableInstances._

implicit val catPrintable: Printable[Cat] = new Printable[Cat] {
  def format(cat: Cat) = {
    val name = Printable.format(cat.name)
    val age = Printable.format(cat.age)
    val color = Printable.format(cat.color)
    s"$name is a $age year-old $color cat."
  }
}
```

Finally, we use the type class by bringing the relevant instances into scope and using interface object/syntax. If we defined the instances in companion objects Scala brings them into scope for us automatically. Otherwise we use an `import` to access them:

```
val cat = Cat("Garfield", 41, "ginger and black")
// cat: Cat = Cat(name = "Garfield", age = 41, color = "ginger and
// black")

Printable.print(cat)
// Garfield is a 41 year-old ginger and black cat.
```

[Return to the exercise](#)

B.3 Printable Library Part 3

First we define an `implicit class` containing our extension methods:

```
object PrintableSyntax {
    implicit class PrintableOps[A](value: A) {
        def format(implicit p: Printable[A]): String =
            p.format(value)

        def print(implicit p: Printable[A]): Unit =
            println(format(p))
    }
}
```

With `PrintableOps` in scope, we can call the imaginary `print` and `format` methods on any value for which Scala can locate an `implicit` instance of `Printable`:

```
import PrintableSyntax._

Cat("Garfield", 41, "ginger and black").print
// Garfield is a 41 year-old ginger and black cat.
```

We get a compile error if we haven't defined an instance of `Printable` for the relevant type:

```

import java.util.Date
new Date().print
// error:
// No given instance of type repl.MdocSession.MdocApp0.Printable[java.
    util.Date] was found for parameter p of method print in class
PrintableOps
// new Date().print
//           ^^^^

```

[Return to the exercise](#)

B.4 Cat Show

First let's import everything we need from Cats: the `Show` type class, the instances for `Int` and `String`, and the interface syntax:

```

import cats.Show
import cats.instances.int._      // for Show
import cats.instances.string._  // for Show
import cats.syntax.show._       // for show

```

Our definition of `Cat` remains the same:

```
final case class Cat(name: String, age: Int, color: String)
```

In the companion object we replace our `Printable` with an instance of `Show` using one of the definition helpers discussed above:

```

implicit val catShow: Show[Cat] = Show.show[Cat] { cat =>
  val name  = cat.name.show
  val age   = cat.age.show
  val color = cat.color.show
  s"$name is a $age year-old $color cat."
}

```

Finally, we use the `Show` interface syntax to print our instance of `Cat`:

```
println(Cat("Garfield", 38, "ginger and black").show)
// Garfield is a 38 year-old ginger and black cat.
```

[Return to the exercise](#)

B.5 Equality, Liberty, and Felinity

First we need our Cats imports. In this exercise we'll be using the `Eq` type class and the `Eq` interface syntax. We'll bring instances of `Eq` into scope as we need them below:

```
import cats.Eq
import cats.syntax.eq._ // for ===
```

Our `Cat` class is the same as ever:

```
final case class Cat(name: String, age: Int, color: String)
```

We bring the `Eq` instances for `Int` and `String` into scope for the implementation of `Eq[Cat]`:

```
import cats.instances.int._    // for Eq
import cats.instances.string._ // for Eq

implicit val catEqual: Eq[Cat] =
  Eq.instance[Cat] { (cat1, cat2) =>
    (cat1.name === cat2.name) &&
    (cat1.age === cat2.age) &&
    (cat1.color === cat2.color)
  }
```

Finally, we test things out in a sample application:

```
val cat1 = Cat("Garfield", 38, "orange and black")
// cat1: Cat = Cat(name = "Garfield", age = 38, color = "orange and
//   black")
val cat2 = Cat("Heathcliff", 32, "orange and black")
```

```
// cat2: Cat = Cat(name = "Heathcliff", age = 32, color = "orange and
// black")

cat1 === cat2
// res15: Boolean = false
cat1 != cat2
// res16: Boolean = true

import cats.instances.option._ // for Eq

val optionCat1 = Option(cat1)
// optionCat1: Option[Cat] = Some(
//   value = Cat(name = "Garfield", age = 38, color = "orange and
//   black")
// )
val optionCat2 = Option.empty[Cat]
// optionCat2: Option[Cat] = None

optionCat1 === optionCat2
// res17: Boolean = false
optionCat1 != optionCat2
// res18: Boolean = true
```

[Return to the exercise](#)

Appendix C

Solutions for: Monoids and Semigroups

C.1 The Truth About Monoids

There are four monoids for Boolean! First, we have *and* with operator `&&` and identity `true`:

```
implicit val booleanAndMonoid: Monoid[Boolean] =
  new Monoid[Boolean] {
    def combine(a: Boolean, b: Boolean) = a && b
    def empty = true
  }
```

Second, we have *or* with operator `||` and identity `false`:

```
implicit val booleanOrMonoid: Monoid[Boolean] =
  new Monoid[Boolean] {
    def combine(a: Boolean, b: Boolean) = a || b
    def empty = false
  }
```

Third, we have *exclusive or* with identity `false`:

```
implicit val booleanEitherMonoid: Monoid[Boolean] =
  new Monoid[Boolean] {
    def combine(a: Boolean, b: Boolean) =
      (a && !b) || (!a && b)

    def empty = false
  }
```

Finally, we have *exclusive nor* (the negation of exclusive or) with identity true:

```
implicit val booleanXnorMonoid: Monoid[Boolean] =
  new Monoid[Boolean] {
    def combine(a: Boolean, b: Boolean) =
      (!a || b) && (a || !b)

    def empty = true
  }
```

Showing that the identity law holds in each case is straightforward. Similarly associativity of the combine operation can be shown by enumerating the cases.

[Return to the exercise](#)

C.2 All Set for Monoids

Set union forms a monoid along with the empty set:

```
implicit def setUnionMonoid[A]: Monoid[Set[A]] =
  new Monoid[Set[A]] {
    def combine(a: Set[A], b: Set[A]) = a union b
    def empty = Set.empty[A]
  }
```

We need to define `setUnionMonoid` as a method rather than a value so we can accept the type parameter `A`. The type parameter allows us to use the same definition to summon Monoids for Sets of any type of data:

```
val intSetMonoid = Monoid[Set[Int]]
val strSetMonoid = Monoid[Set[String]]

intSetMonoid.combine(Set(1, 2), Set(2, 3))
// res18: Set[Int] = Set(1, 2, 3)
strSetMonoid.combine(Set("A", "B"), Set("B", "C"))
// res19: Set[String] = Set("A", "B", "C")
```

Set intersection forms a semigroup, but doesn't form a monoid because it has no identity element:

```
implicit def setIntersectionSemigroup[A]: Semigroup[Set[A]] =
  new Semigroup[Set[A]] {
    def combine(a: Set[A], b: Set[A]) =
      a intersect b
  }
```

Set complement and set difference are not associative, so they cannot be considered for either monoids or semigroups. However, symmetric difference (the union less the intersection) does also form a monoid with the empty set:

```
implicit def symDiffMonoid[A]: Monoid[Set[A]] =
  new Monoid[Set[A]] {
    def combine(a: Set[A], b: Set[A]): Set[A] =
      (a diff b) union (b diff a)
    def empty: Set[A] = Set.empty
  }
```

[Return to the exercise](#)

C.3 Adding All The Things

We can write the addition as a `foldLeft` using `0` and the `+` operator:

```
def add(items: List[Int]): Int =
  items.foldLeft(0)(_ + _)
```

We can alternatively write the fold using `Monoids`, although there's not a compelling use case for this yet:

```
import cats.Monoid
import cats.instances.int._    // for Monoid
import cats.syntax.semigroup._ // for |+|
```

```
def add(items: List[Int]): Int =
  items.foldLeft(Monoid[Int].empty)(_ |+_ _)
```

[Return to the exercise](#)

C.4 Adding All The Things Part 2

Now there is a use case for `Monoids`. We need a single method that adds `Ints` and instances of `Option[Int]`. We can write this as a generic method that accepts an implicit `Monoid` as a parameter:

```
import cats.Monoid
import cats.syntax.semigroup._ // for |+|
```

```
def add[A](items: List[A])(implicit monoid: Monoid[A]): A =
  items.foldLeft(monoid.empty)(_ |+_ _)
```

We can optionally use Scala's `context bound` syntax to write the same code in a shorter way:

```
def add[A: Monoid](items: List[A]): A =
  items.foldLeft(Monoid[A].empty)(_ |+_ _)
```

We can use this code to add values of type `Int` and `Option[Int]` as requested:

```
import cats.instances.int._ // for Monoid
```

```
add(List(1, 2, 3))
// res10: Int = 6
```

```
import cats.instances.option._ // for Monoid

add(List(Some(1), None, Some(2), None, Some(3)))
// res11: Option[Int] = Some(value = 6)
```

Note that if we try to add a list consisting entirely of `Some` values, we get a compile error:

```
add(List(Some(1), Some(2), Some(3)))
// error:
// No given instance of type cats.kernel.Monoid[Some[Int]] was found
// for an implicit parameter of method add in object MdocApp2
// implicit val monoid: Monoid[Order] = new Monoid[Order] {
// }
```

This happens because the inferred type of the list is `List[Some[Int]]`, while Cats will only generate a `Monoid` for `Option[Int]`. We'll see how to get around this in a moment.

[Return to the exercise](#)

C.5 Adding All The Things Part 3

Easy—we simply define a monoid instance for `Order`!

```
implicit val monoid: Monoid[Order] = new Monoid[Order] {
  def combine(o1: Order, o2: Order) =
    Order(
      o1.totalCost + o2.totalCost,
      o1.quantity + o2.quantity
    )
  def empty = Order(0, 0)
}
```

[Return to the exercise](#)

Appendix D

Solutions for: Functors

D.1 Branching out with Functors

The semantics are similar to writing a Functor for `List`. We recurse over the data structure, applying the function to every `Leaf` we find. The functor laws intuitively require us to retain the same structure with the same pattern of `Branch` and `Leaf` nodes:

```
import cats.Functor

implicit val treeFunctor: Functor[Tree] =
  new Functor[Tree] {
    def map[A, B](tree: Tree[A])(func: A => B): Tree[B] =
      tree match {
        case Branch(left, right) =>
          Branch(map(left)(func), map(right)(func))
        case Leaf(value) =>
          Leaf(func(value))
      }
  }
```

Let's use our Functor to transform some Trees:

```
Branch(Leaf(10), Leaf(20)).map(_ * 2)
// error:
// value map is not a member of repl.MdocSession.MdocApp0.Branch[Int]
//     Branch(left, right)
//     ^
```

Oops! This falls foul of the same invariance problem we discussed in Section 3.6.1. The compiler can find a Functor instance for Tree but not for Branch or Leaf. Let's add some smart constructors to compensate:

```
object Tree {
  def branch[A](left: Tree[A], right: Tree[A]): Tree[A] =
    Branch(left, right)

  def leaf[A](value: A): Tree[A] =
    Leaf(value)
}
```

Now we can use our Functor properly:

```
Tree.leaf(100).map(_ * 2)
// res9: Tree[Int] = Leaf(value = 200)

Tree.branch(Tree.leaf(10), Tree.leaf(20)).map(_ * 2)
// res10: Tree[Int] = Branch(left = Leaf(value = 20), right = Leaf(
  value = 40))
```

[Return to the exercise](#)

D.2 Showing off with Contramap

Here's a working implementation. We call `func` to turn the `B` into an `A` and then use our original `Printable` to turn the `A` into a `String`. In a small show of sleight of hand we use a `self` alias to distinguish the outer and inner `Printables`:

```
trait Printable[A] { self =>

    def format(value: A): String

    def contramap[B](func: B => A): Printable[B] =
        new Printable[B] {
            def format(value: B): String =
                self.format(func(value))
        }
}

def format[A](value: A)(implicit p: Printable[A]): String =
    p.format(value)
```

[Return to the exercise](#)

D.3 Showing off with Contramap Part 2

To make the instance generic across all types of Box, we base it on the `Printable` for the type inside the Box. We can either write out the complete definition by hand:

```
implicit def boxPrintable[A](
    implicit p: Printable[A])
: Printable[Box[A]] =
    new Printable[Box[A]] {
        def format(box: Box[A]): String =
            p.format(box.value)
    }
```

or use `contramap` to base the new instance on the implicit parameter:

```
implicit def boxPrintable[A](implicit p: Printable[A]): Printable[Box[A]] =
    p.contramap[Box[A]](_.value)
```

Using `contramap` is much simpler, and conveys the functional programming approach of building solutions by combining simple building blocks using pure functional combinators.

[Return to the exercise](#)

D.4 Transformative Thinking with imap

Here's a working implementation:

```
trait Codec[A] { self =>
  def encode(value: A): String
  def decode(value: String): A

  def imap[B](dec: A => B, enc: B => A): Codec[B] = {
    new Codec[B] {
      def encode(value: B): String =
        self.encode(enc(value))

      def decode(value: String): B =
        dec(self.decode(value))
    }
  }
}
```

[Return to the exercise](#)

D.5 Transformative Thinking with imap Part 2

We can implement this using the `imap` method of `stringCodec`:

```
implicit val doubleCodec: Codec[Double] =
  stringCodec imap[Double](_.toDouble, _.toString)
```

[Return to the exercise](#)

D.6 Transformative Thinking with imap Part 3

We need a generic `Codec` for `Box[A]` for any given `A`. We create this by calling `imap` on a `Codec[A]`, which we bring into scope using an implicit parameter:

```
implicit def boxCodec[A](implicit c: Codec[A]): Codec[Box[A]] =  
  c imap[Box[A]](Box(_), _.value)
```

[Return to the exercise](#)

Appendix E

Solutions for: Monads

E.1 Getting Func-y

At first glance this seems tricky, but if we follow the types we'll see there's only one solution. We are passed a value of type $F[A]$. Given the tools available there's only one thing we can do: call `flatMap`:

```
trait Monad[F[_]] {
    def pure[A](value: A): F[A]

    def flatMap[A, B](value: F[A])(func: A => F[B]): F[B]

    def map[A, B](value: F[A])(func: A => B): F[B] =
        flatMap(value)(a => ???)
}
```

We need a function of type $A \Rightarrow F[B]$ as the second parameter. We have two function building blocks available: the `func` parameter of type $A \Rightarrow B$ and the `pure` function of type $A \Rightarrow F[A]$. Combining these gives us our result:

```
trait Monad[F[_]] {
    def pure[A](value: A): F[A]
```

```
def flatMap[A, B](value: F[A])(func: A => F[B]): F[B]

def map[A, B](value: F[A])(func: A => B): F[B] =
    flatMap(value)(a => pure(func(a)))
}
```

[Return to the exercise](#)

E.2 Monadic Secret Identities

Let's start by defining the method signatures:

```
import cats.Id

def pure[A](value: A): Id[A] =
    ???

def map[A, B](initial: Id[A])(func: A => B): Id[B] =
    ???

def flatMap[A, B](initial: Id[A])(func: A => Id[B]): Id[B] =
    ???
```

Now let's look at each method in turn. The `pure` operation creates an `Id[A]` from an `A`. But `A` and `Id[A]` are the same type! All we have to do is return the initial value:

```
def pure[A](value: A): Id[A] =
    value

pure(123)
// res7: Int = 123
```

The `map` method takes a parameter of type `Id[A]`, applies a function of type `A => B`, and returns an `Id[B]`. But `Id[A]` is simply `A` and `Id[B]` is simply `B`! All we have to do is call the function—no boxing or unboxing required:

```
def map[A, B](initial: Id[A])(func: A => B): Id[B] =  
  func(initial)  
  
map(123)(_ * 2)  
// res8: Int = 246
```

The final punch line is that, once we strip away the `Id` type constructors, `flatMap` and `map` are actually identical:

```
def flatMap[A, B](initial: Id[A])(func: A => Id[B]): Id[B] =  
  func(initial)  
  
flatMap(123)(_ * 2)  
// res9: Int = 246
```

This ties in with our understanding of functors and monads as sequencing type classes. Each type class allows us to sequence operations ignoring some kind of complication. In the case of `Id` there is no complication, making `map` and `flatMap` the same thing.

Notice that we haven't had to write type annotations in the method bodies above. The compiler is able to interpret values of type `A` as `Id[A]` and vice versa by the context in which they are used.

The only restriction we've seen to this is that Scala cannot unify types and type constructors when searching for implicits. Hence our need to re-type `Int` as `Id[Int]` in the call to `sumSquare` at the opening of this section:

```
sumSquare(3 : Id[Int], 4 : Id[Int])
```

[Return to the exercise](#)

E.3 What is Best?

This is an open question. It's also kind of a trick question—the answer depends on the semantics we're looking for. Some points to ponder:

- Error recovery is important when processing large jobs. We don't want to run a job for a day and then find it failed on the last element.
- Error reporting is equally important. We need to know what went wrong, not just that something went wrong.
- In a number of cases, we want to collect all the errors, not just the first one we encountered. A typical example is validating a web form. It's a far better experience to report all errors to the user when they submit a form than to report them one at a time.

[Return to the exercise](#)

E.4 Abstracting

We can solve this using `pure` and `raiseError`. Note the use of type parameters to these methods, to aid type inference.

```
def validateAdult[F[_]](age: Int)(implicit me: MonadError[F, Throwable]): F[Int] =  
  if(age >= 18) age.pure[F]  
  else new IllegalArgumentException("Age must be greater than or equal  
    to 18").raiseError[F, Int]
```

[Return to the exercise](#)

E.5 Safer Folding using Eval

The easiest way to fix this is to introduce a helper method called `foldRightEval`. This is essentially our original method with every occurrence of `B` replaced with `Eval[B]`, and a call to `Eval.defer` to protect the recursive call:

```
import cats.Eval

def foldRightEval[A, B](as: List[A], acc: Eval[B])
  (fn: (A, Eval[B]) => Eval[B]): Eval[B] =
  as match {
    case head :: tail =>
      Eval.defer(fn(head, foldRightEval(tail, acc))(fn))
    case Nil =>
      acc
  }
```

We can redefine `foldRight` simply in terms of `foldRightEval` and the resulting method is stack safe:

```
def foldRight[A, B](as: List[A], acc: B)(fn: (A, B) => B): B =
  foldRightEval(as, Eval.now(acc)) { (a, b) =>
    b.map(fn(a, _))
  }.value

foldRight((1 to 100000).toList, 0L)(_ + _)
// res24: Long = 5000050000L
```

[Return to the exercise](#)

E.6 Show Your Working

We'll start by defining a type alias for `Writer` so we can use it with pure syntax:

```
import cats.data.Writer
import cats.instances.vector.~
import cats.syntax.applicative._ // for pure

type Logged[A] = Writer[Vector[String], A]

42.pure[Logged]
// res11: WriterT[Id, Vector[String], Int] = WriterT(run = (Vector(),
  42))
```

We'll import the `tell` syntax as well:

```
import cats.syntax.writer._ // for tell

Vector("Message").tell
// res12: WriterT[Id, Vector[String], Unit] = WriterT(
//   run = (Vector("Message"), ())
// )
```

Finally, we'll import the `Semigroup` instance for `Vector`. We need this to `map` and `flatMap` over `Logged`:

```
import cats.instances.vector._ // for Monoid

41.pure[Logged].map(_ + 1)
// res13: WriterT[Id, Vector[String], Int] = WriterT(run = (Vector(),
//   42))
```

With these in scope, the definition of `factorial` becomes:

```
def factorial(n: Int): Logged[Int] =
  for {
    ans <- if(n == 0) {
      1.pure[Logged]
    } else {
      slowly(factorial(n - 1).map(_ * n))
    }
    _   <- Vector(s"fact $n $ans").tell
  } yield ans
```

When we call `factorial`, we now have to `run` the return value to extract the log and our factorial:

```
val (log, res) = factorial(5).run
// log: Vector[String] = Vector(
//   "fact 0 1",
//   "fact 1 1",
//   "fact 2 2",
//   "fact 3 6",
//   "fact 4 24",
//   "fact 5 120"
// )
```

```
// res: Int = 120
```

We can run several factorials in parallel as follows, capturing their logs independently without fear of interleaving:

```
Await.result(Future.sequence(Vector(
  Future(factorial(5)),
  Future(factorial(5))
)).map(_.map(_.written)), 5.seconds)
// res: scala.collection.immutable.Vector[cats.Id[Vector[String]]] =
//   Vector(
//     Vector(fact 0 1, fact 1 1, fact 2 2, fact 3 6, fact 4 24, fact
//       5 120),
//     Vector(fact 0 1, fact 1 1, fact 2 2, fact 3 6, fact 4 24, fact
//       5 120)
//   )
```

[Return to the exercise](#)

E.7 Hacking on Readers

Our type alias fixes the `Db` type but leaves the result type flexible:

```
type DbReader[A] = Reader[Db, A]
```

[Return to the exercise](#)

E.8 Hacking on Readers Part 2

Remember: the idea is to leave injecting the configuration until last. This means setting up functions that accept the config as a parameter and check it against the concrete user info we have been given:

```
def findUsername(userId: Int): DbReader[Option[String]] =
  Reader(db => db.usernames.get(userId))

def checkPassword(
  username: String,
  password: String): DbReader[Boolean] =
  Reader(db => db.passwords.get(username).contains(password))
```

[Return to the exercise](#)

E.9 Hacking on Readers Part 3

As you might expect, here we use `flatMap` to chain `findUsername` and `checkPassword`. We use `pure` to lift a Boolean to a `DbReader[Boolean]` when the username is not found:

```
import cats.syntax.applicative._ // for pure

def checkLogin(
  userId: Int,
  password: String): DbReader[Boolean] =
  for {
    username   <- findUsername(userId)
    passwordOk <- username.map { username =>
      checkPassword(username, password)
    }.getOrElse {
      false.pure[DbReader]
    }
  } yield passwordOk
```

[Return to the exercise](#)

E.10 Post-Order Calculator

The stack operation required is different for operators and operands. For clarity we'll implement `evalOne` in terms of two helper functions, one for each case:

```
def evalOne(sym: String): CalcState[Int] =
  sym match {
    case "+" => operator(_ + _)
    case "-" => operator(_ - _)
    case "*" => operator(_ * _)
    case "/" => operator(_ / _)
    case num => operand(num.toInt)
  }
```

Let's look at `operand` first. All we have to do is push a number onto the stack. We also return the operand as an intermediate result:

```
def operand(num: Int): CalcState[Int] =
  State[List[Int], Int] { stack =>
    (num :: stack, num)
  }
```

The `operator` function is a little more complex. We have to pop two operands off the stack (having the second operand at the top of the stack) and push the result in their place. The code can fail if the stack doesn't have enough operands on it, but the exercise description allows us to throw an exception in this case:

```
def operator(func: (Int, Int) => Int): CalcState[Int] =
  State[List[Int], Int] {
    case b :: a :: tail =>
      val ans = func(a, b)
      (ans :: tail, ans)

    case _ =>
      sys.error("Fail!")
  }
```

[Return to the exercise](#)

E.11 Post-Order Calculator Part 2

We implement `evalAll` by folding over the input. We start with a pure `CalcState` that returns `0` if the list is empty. We `flatMap` at each stage, ignoring

the intermediate results as we saw in the example:

```
import cats.syntax.applicative._ // for pure

def evalAll(input: List[String]): CalcState[Int] =
  input.foldLeft(0.pure[CalcState]) { (a, b) =>
    a.flatMap(_ => evalOne(b))
}
```

[Return to the exercise](#)

E.12 Post-Order Calculator Part 3

We've done all the hard work now. All we need to do is split the input into terms and call `runA` and `value` to unpack the result:

```
def evalInput(input: String): Int =
  evalAll(input.split(" ").toList).runA(Nil).value

evalInput("1 2 + 3 4 + *")
// res15: Int = 21
```

[Return to the exercise](#)

E.13 Branching out Further with Monads

The code for `flatMap` is similar to the code for `map`. Again, we recurse down the structure and use the results from `func` to build a new Tree.

The code for `tailRecM` is fairly complex regardless of whether we make it tail-recursive or not.

If we follow the types, the non-tail-recursive solution falls out:

```
import cats.Monad

implicit val treeMonad: Monad[Tree] = new Monad[Tree] {
  def pure[A](value: A): Tree[A] =
    Leaf(value)

  def flatMap[A, B](tree: Tree[A])
    (func: A => Tree[B]): Tree[B] =
    tree match {
      case Branch(l, r) =>
        Branch(flatMap(l)(func), flatMap(r)(func))
      case Leaf(value) =>
        func(value)
    }

  def tailRecM[A, B](a: A)(func: A => Tree[Either[A, B]]): Tree[B] = {
    flatMap(func(a)) {
      case Left(value) =>
        tailRecM(value)(func)
      case Right(value) =>
        Leaf(value)
    }
  }
}
```

The solution above is perfectly fine for this exercise. Its only downside is that Cats cannot make guarantees about stack safety.

The tail-recursive solution is much harder to write. We adapted this solution from [this Stack Overflow post](#) by Nazarii Bardiuk. It involves an explicit depth first traversal of the tree, maintaining an open list of nodes to visit and a closed list of nodes to use to reconstruct the tree:

```
import cats.Monad
import scala.annotation.tailrec

implicit val treeMonad: Monad[Tree] = new Monad[Tree] {
  def pure[A](value: A): Tree[A] =
    Leaf(value)

  def flatMap[A, B](tree: Tree[A])
```

```

(func: A => Tree[B]): Tree[B] =
tree match {
  case Branch(l, r) =>
    Branch(flatMap(l)(func), flatMap(r)(func))
  case Leaf(value)  =>
    func(value)
}

def tailRecM[A, B](arg: A)
  (func: A => Tree[Either[A, B]]): Tree[B] = {
@tailrec
def loop(
  open: List[Tree[Either[A, B]]],
  closed: List[Option[Tree[B]]]): List[Tree[B]] =
open match {
  case Branch(l, r) :: next =>
    loop(l :: r :: next, None :: closed)

  case Leaf(Left(value)) :: next =>
    loop(func(value)) :: next, closed)

  case Leaf(Right(value)) :: next =>
    loop(next, Some(pure(value))) :: closed)

  case Nil =>
    closed.foldLeft(Nil: List[Tree[B]]) { (acc, maybeTree) =>
      maybeTree.map(_ :: acc).getOrElse {
        acc match {
          case left :: right :: tail => branch(left, right) :: tail
        }
      }
    }
}

loop(List(func(arg)), Nil).head
}
}

```

Regardless of which version of `tailRecM` we define, we can use our Monad to `flatMap` and `map` on Trees:

```
import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatMap

branch(leaf(100), leaf(200)).
  flatMap(x => branch(leaf(x - 1), leaf(x + 1)))
// res5: Tree[Int] = Branch(
//   left = Branch(left = Leaf(value = 99), right = Leaf(value = 101))
//
//   right = Branch(left = Leaf(value = 199), right = Leaf(value =
// 201))
// )
```

We can also transform Trees using for comprehensions:

```
for {
  a <- branch(leaf(100), leaf(200))
  b <- branch(leaf(a - 10), leaf(a + 10))
  c <- branch(leaf(b - 1), leaf(b + 1))
} yield c
// res6: Tree[Int] = Branch(
//   left = Branch(
//     left = Branch(left = Leaf(value = 89), right = Leaf(value = 91)
//   ),
//     right = Branch(left = Leaf(value = 109), right = Leaf(value =
// 111))
//   ),
//   right = Branch(
//     left = Branch(left = Leaf(value = 189), right = Leaf(value =
// 191)),
//     right = Branch(left = Leaf(value = 209), right = Leaf(value =
// 211))
//   )
// )
```

The monad for `Option` provides fail-fast semantics. The monad for `List` provides concatenation semantics. What are the semantics of `flatMap` for a binary tree? Every node in the tree has the potential to be replaced with a whole subtree, producing a kind of “growing” or “feathering” behaviour, reminiscent of list concatenation along two axes.

[Return to the exercise](#)

Appendix F

Solutions for: Monad Transformers

F.1 Monads: Transform and Roll Out

This is a relatively simple combination. We want `Future` on the outside and `Either` on the inside, so we build from the inside out using an `EitherT` of `Future`:

```
import cats.data.EitherT
import scala.concurrent.Future

type Response[A] = EitherT[Future, String, A]
```

[Return to the exercise](#)

F.2 Monads: Transform and Roll Out Part 2

```
import cats.data.EitherT
import scala.concurrent.Future
val powerLevels = Map(
  "Jazz"      -> 6,
  "Bumblebee" -> 8,
```

```

    "Hot Rod"    -> 10
}

import cats.instances.future._ // for Monad
import scala.concurrent.ExecutionContext.Implicits.global

type Response[A] = EitherT[Future, String, A]

def getPowerLevel(ally: String): Response[Int] = {
  powerLevels.get(ally) match {
    case Some(avg) => EitherT.right(Future(avg))
    case None        => EitherT.left(Future(s"$ally unreachable"))
  }
}

```

[Return to the exercise](#)

F.3 Monads: Transform and Roll Out Part 3

We request the power level from each ally and use `map` and `flatMap` to combine the results:

```

def canSpecialMove(ally1: String, ally2: String): Response[Boolean] =
  for {
    power1 <- getPowerLevel(ally1)
    power2 <- getPowerLevel(ally2)
  } yield (power1 + power2) > 15

```

[Return to the exercise](#)

F.4 Monads: Transform and Roll Out Part 4

We use the `value` method to unpack the monad stack and `Await` and `fold` to unpack the `Future` and `Either`:

```
import scala.concurrent.Await
import scala.concurrent.ExecutionContext.Implicits.global
import scala.concurrent.duration._

def canSpecialMove(ally1: String, ally2: String): Response[Boolean] =
  for {
    power1 <- getPowerLevel(ally1)
    power2 <- getPowerLevel(ally2)
  } yield (power1 + power2) > 15

def tacticalReport(ally1: String, ally2: String): String = {
  val stack = canSpecialMove(ally1, ally2).value

  Await.result(stack, 1.second) match {
    case Left(msg) =>
      s"Comms error: $msg"
    case Right(true)  =>
      s"$ally1 and $ally2 are ready to roll out!"
    case Right(false) =>
      s"$ally1 and $ally2 need a recharge."
  }
}
```

[Return to the exercise](#)

Appendix G

Solutions for: Semigroupal and Applicative

G.1 The Product of Lists

This exercise is checking that you understood the definition of product in terms of `flatMap` and `map`.

```
import cats.syntax.functor._ // for map
import cats.syntax.flatMap._ // for flatMap

def product[F[_]: Monad, A, B](x: F[A], y: F[B]): F[(A, B)] =
  x.flatMap(a => y.map(b => (a, b)))
```

This code is equivalent to a for comprehension:

```
def product[F[_]: Monad, A, B](x: F[A], y: F[B]): F[(A, B)] =
  for {
    a <- x
    b <- y
  } yield (a, b)
```

The semantics of `flatMap` are what give rise to the behaviour for `List` and `Either`:

```
import cats.instances.list._ // for Semigroupal

product(List(1, 2), List(3, 4))
// res9: List[Tuple2[Int, Int]] = List((1, 3), (1, 4), (2, 3), (2, 4))
```

[Return to the exercise](#)

G.2 Parallel List

List does have a Parallel instance, and it zips the List instead of creating the cartesian product.

We can see by writing a little bit of code.

```
import cats.instances.list._

(List(1, 2), List(3, 4)).tupled
// res8: List[Tuple2[Int, Int]] = List((1, 3), (1, 4), (2, 3), (2, 4))
(List(1, 2), List(3, 4)).parTupled
// res9: List[Tuple2[Int, Int]] = List((1, 3), (2, 4))
```

[Return to the exercise](#)

Appendix H

Solutions for: Foldable and Traverse

H.1 Reflecting on Folds

Folding from left to right reverses the list:

```
List(1, 2, 3).foldLeft(List.empty[Int])((a, i) => i :: a)
// res6: List[Int] = List(3, 2, 1)
```

Folding right to left copies the list, leaving the order intact:

```
List(1, 2, 3).foldRight(List.empty[Int])((i, a) => i :: a)
// res7: List[Int] = List(1, 2, 3)
```

Note that we have to carefully specify the type of the accumulator to avoid a type error. We use `List.empty[Int]` to avoid inferring the accumulator type as `Nil.type` or `List[Nothing]`:

```
List(1, 2, 3).foldRight(Nil)(_ :: _)
// error:
// Found:    List[Int]
```

```
// Required: scala.collection.immutable.Nil.type
//   list.foldRight(List.empty[B]) { (item, accum) =>
//     ^
// }
```

[Return to the exercise](#)

H.2 Scaf-fold-ing Other Methods

Here are the solutions:

```
def map[A, B](list: List[A])(func: A => B): List[B] =
  list.foldRight(List.empty[B]) { (item, accum) =>
    func(item) :: accum
  }

map(List(1, 2, 3))(_ * 2)
// res9: List[Int] = List(2, 4, 6)

def flatMap[A, B](list: List[A])(func: A => List[B]): List[B] =
  list.foldRight(List.empty[B]) { (item, accum) =>
    func(item) :::: accum
  }

flatMap(List(1, 2, 3))(a => List(a, a * 10, a * 100))
// res10: List[Int] = List(1, 10, 100, 2, 20, 200, 3, 30, 300)

def filter[A](list: List[A])(func: A => Boolean): List[A] =
  list.foldRight(List.empty[A]) { (item, accum) =>
    if(func(item)) item :: accum else accum
  }

filter(List(1, 2, 3))(_ % 2 == 1)
// res11: List[Int] = List(1, 3)
```

We've provided two definitions of `sum`, one using `scala.math.Numeric` (which recreates the built-in functionality accurately)...

```
import scala.math.Numeric

def sumWithNumeric[A](list: List[A])
    (implicit numeric: Numeric[A]): A =
  list.foldRight(numeric.zero)(numeric.plus)

sumWithNumeric(List(1, 2, 3))
// res12: Int = 6
```

and one using `cats.Monoid` (which is more appropriate to the content of this book):

```
import cats.Monoid

def sumWithMonoid[A](list: List[A])
    (implicit monoid: Monoid[A]): A =
  list.foldRight(monoid.empty)(monoid.combine)

import cats.instances.int._ // for Monoid

sumWithMonoid(List(1, 2, 3))
// res13: Int = 6
```

[Return to the exercise](#)

H.3 Traversing with Vectors

The argument is of type `List[Vector[Int]]`, so we're using the `Applicative` for `Vector` and the return type is going to be `Vector[List[Int]]`.

`Vector` is a monad, so its semigroupal `combine` function is based on `flatMap`. We'll end up with a `Vector` of `Lists` of all the possible combinations of `List(1, 2)` and `List(3, 4)`:

```
listSequence(List(Vector(1, 2), Vector(3, 4)))
// res7: Vector[List[Int]] = Vector(
//   List(1, 3),
//   List(1, 4),
```

```
//  List(2, 3),
//  List(2, 4)
// )
```

[Return to the exercise](#)

H.4 Traversing with Vectors Part 2

With three items in the input list, we end up with combinations of three `Int`s: one from the first item, one from the second, and one from the third:

```
listSequence(List(Vector(1, 2), Vector(3, 4), Vector(5, 6)))
// res9: Vector[List[Int]] = Vector(
//   List(1, 3, 5),
//   List(1, 3, 6),
//   List(1, 4, 5),
//   List(1, 4, 6),
//   List(2, 3, 5),
//   List(2, 3, 6),
//   List(2, 4, 5),
//   List(2, 4, 6)
// )
```

[Return to the exercise](#)

H.5 Traversing with Options

The arguments to `listTraverse` are of types `List[Int]` and `Int => Option[Int]`, so the return type is `Option[List[Int]]`. Again, `Option` is a monad, so the semigroupal `combine` function follows from `flatMap`. The semantics are therefore fail-fast error handling: if all inputs are even, we get a list of outputs. Otherwise we get `None`:

```
process(List(2, 4, 6))
// res12: Option[List[Int]] = Some(value = List(2, 4, 6))
process(List(1, 2, 3))
// res13: Option[List[Int]] = None
```

[Return to the exercise](#)

H.6 Traversing with Validated

The return type here is `ErrorsOr[List[Int]]`, which expands to `Validated[List[String], List[Int]]`. The semantics for semigroupal combine on validated are accumulating error handling, so the result is either a list of even Ints, or a list of errors detailing which Ints failed the test:

```
process(List(2, 4, 6))
// res17: Validated[List[String], List[Int]] = Valid(a = List(2, 4, 6)
// )
process(List(1, 2, 3))
// res18: Validated[List[String], List[Int]] = Invalid(
//   e = List("1 is not even", "3 is not even")
// )
```

[Return to the exercise](#)

Appendix I

Solutions for: Case Study: Testing Asynchronous Code

I.1 Abstracting over Type Constructors

Here's the implementation:

```
import cats.Id

trait UptimeClient[F[_]] {
  def getUptime(hostname: String): F[Int]
}

trait RealUptimeClient extends UptimeClient[Future] {
  def getUptime(hostname: String): Future[Int]
}

trait TestUptimeClient extends UptimeClient[Id] {
  def getUptime(hostname: String): Id[Int]
}
```

Note that, because `Id[A]` is just a simple alias for `A`, we don't need to refer to the type in `TestUptimeClient` as `Id[Int]`—we can simply write `Int` instead:

```
trait TestUptimeClient extends UptimeClient[Id] {
  def getUptime(hostname: String): Int
}
```

Of course, technically speaking we don't need to redeclare `getUptime` in `RealUptimeClient` or `TestUptimeClient`. However, writing everything out helps illustrate the technique.

[Return to the exercise](#)

I.2 Abstracting over Type Constructors Part 2

The final code is similar to our original implementation of `TestUptimeClient`, except we no longer need the call to `Future.successful`:

```
class TestUptimeClient(hosts: Map[String, Int])
  extends UptimeClient[Id] {
  def getUptime(hostname: String): Int =
    hosts.getOrElse(hostname, 0)
}
```

[Return to the exercise](#)

I.3 Abstracting over Monads

The code should look like this:

```
class UptimeService[F[_]](client: UptimeClient[F]) {
  def getTotalUptime(hostnames: List[String]): F[Int] =
    ???  

    // hostnames.traverse(client.getUptime).map(_.sum)
}
```

[Return to the exercise](#)

I.4 Abstracting over Monads Part 2

We can write this as an implicit parameter:

```
import cats.Applicative
import cats.syntax.functor._ // for map

class UptimeService[F[_]](client: UptimeClient[F])
  (implicit a: Applicative[F]) {

  def getTotalUptime(hostnames: List[String]): F[Int] =
    hostnames.traverse(client.getUptime).map(_.sum)
}
```

or more tersely as a context bound:

```
class UptimeService[F[_]: Applicative]
  (client: UptimeClient[F]) {

  def getTotalUptime(hostnames: List[String]): F[Int] =
    hostnames.traverse(client.getUptime).map(_.sum)
}
```

Note that we need to import `cats.syntax.functor` as well as `cats.Applicative`. This is because we're switching from using `future.map` to the Cats' generic extension method that requires an implicit `Functor` parameter.

[Return to the exercise](#)

Appendix J

Solutions for: Case Study: Map-Reduce

J.1 Implementing foldMap

```
import cats.Monoid

/** Single-threaded map-reduce function.
 * Maps `func` over `values` and reduces using a `Monoid[B]`.
 */
def foldMap[A, B: Monoid](values: Vector[A])(func: A => B): B =  
???
```

[Return to the exercise](#)

J.2 Implementing foldMap Part 2

We have to modify the type signature to accept a `Monoid` for `B`. With that change we can use the `Monoid` `empty` and `|+|` syntax as described in Section 4.5.3:

```
import cats.Monoid
import cats.syntax.semigroup._ // for |+|
```

```
def foldMap[A, B : Monoid](as: Vector[A])(func: A => B): B =
  as.map(func).foldLeft(Monoid[B].empty)(_ |+| _)
```

We can make a slight alteration to this code to do everything in one step:

```
def foldMap[A, B : Monoid](as: Vector[A])(func: A => B): B =
  as.foldLeft(Monoid[B].empty)(_ |+| func(_))
```

[Return to the exercise](#)

J.3 Implementing parallelFoldMap

Here is an annotated solution that splits out each `map` and `fold` into a separate line of code:

```
def parallelFoldMap[A, B: Monoid]
  (values: Vector[A])
  (func: A => B): Future[B] = {
  // Calculate the number of items to pass to each CPU:
  val numCores = Runtime.getRuntime.availableProcessors
  val groupSize = (1.0 * values.size / numCores).ceil.toInt

  // Create one group for each CPU:
  val groups: Iterator[Vector[A]] =
    values.grouped(groupSize)

  // Create a future to foldMap each group:
  val futures: Iterator[Future[B]] =
    groups map { group =>
      Future {
        group.foldLeft(Monoid[B].empty)(_ |+| func(_))
      }
    }

  // foldMap over the groups to calculate a final result:
  Future.sequence(futures) map { iterable =>
```

```
    iterable.foldLeft(Monoid[B].empty)(_ |+_ _)
  }
}

val result: Future[Int] =
  parallelFoldMap((1 to 1000000).toVector)(identity)

Await.result(result, 1.second)
// res14: Int = 1784293664
```

We can re-use our definition of `foldMap` for a more concise solution. Note that the local maps and reduces in steps 3 and 4 of Figure 11.4 are actually equivalent to a single call to `foldMap`, shortening the entire algorithm as follows:

```
def parallelFoldMap[A, B: Monoid]
  (values: Vector[A])
  (func: A => B): Future[B] = {
  val numCores = Runtime.getRuntime.availableProcessors
  val groupSize = (1.0 * values.size / numCores).ceil.toInt

  val groups: Iterator[Vector[A]] =
    values.grouped(groupSize)

  val futures: Iterator[Future[B]] =
    groups.map(group => Future(foldMap(group))(func))

  Future.sequence(futures) map { iterable =>
    iterable.foldLeft(Monoid[B].empty)(_ |+_ _)
  }
}

val result: Future[Int] =
  parallelFoldMap((1 to 1000000).toVector)(identity)

Await.result(result, 1.second)
// res16: Int = 1784293664
```

[Return to the exercise](#)

J.4 parallelFoldMap with more Cats

We'll restate all of the necessary imports for completeness:

```
import cats.Monoid

import cats.instances.int._      // for Monoid
import cats.instances.future._  // for Applicative and Monad
import cats.instances.vector._  // for Foldable and Traversable

import cats.syntax.foldable._   // for combineAll and foldMap
import cats.syntax.traverse._   // for traverse

import scala.concurrent._       ...
import scala.concurrent.duration._ ...
import scala.concurrent.ExecutionContext.Implicits.global
```

Here's the implementation of `parallelFoldMap` delegating as much of the method body to Cats as possible:

```
def parallelFoldMap[A, B: Monoid]
  (values: Vector[A])
  (func: A => B): Future[B] = {
  val numCores = Runtime.getRuntime.availableProcessors
  val groupSize = (1.0 * values.size / numCores).ceil.toInt

  values
    .grouped(groupSize)
    .toVector
    .traverse(group => Future(group.toVector.foldMap(func)))
    .map(_.combineAll)
}

val future: Future[Int] =
  parallelFoldMap((1 to 1000).toVector)(_ * 1000)

Await.result(future, 1.second)
// res18: Int = 500500000
```

The call `toVector.grouped` returns an `Iterable[Iterator[Int]]`. We sprinkle calls to `toVector` through the code to convert the data back to a form that Cats

can understand. The call to `traverse` creates a `Future[Vector[Int]]` containing one `Int` per batch. The call to `map` then combines the `match` using the `combineAll` method from `Foldable`.

[Return to the exercise](#)

Appendix K

Solutions for: Case Study: Data Validation

K.1 Basic Combinators

We need a `Semigroup` for `E`. Then we can combine values of `E` using the `combine` method or its associated `|+|` syntax:

```
import cats.Semigroup
import cats.instances.list._    // for Semigroup
import cats.syntax.semigroup._ // for |+|  
  
val semigroup = Semigroup[List[String]]  
  
// Combination using methods on Semigroup
semigroup.combine(List("Badness"), List("More badness"))
// res3: List[String] = List("Badness", "More badness")  
  
// Combination using Semigroup syntax
List("Oh noes") |+| List("Fail happened")
// res4: List[String] = List("Oh noes", "Fail happened")
```

Note we don't need a full `Monoid` because we don't need the identity element. We should always try to keep our constraints as small as possible!

[Return to the exercise](#)

K.2 Basic Combinators Part 2

We want to report all the errors we can, so we should prefer *not* short-circuiting whenever possible.

In the case of the `and` method, the two checks we're combining are independent of one another. We can always run both rules and combine any errors we see.

[Return to the exercise](#)

K.3 Basic Combinators Part 3

There are at least two implementation strategies.

In the first we represent checks as functions. The `Check` data type becomes a simple wrapper for a function that provides our library of combinator methods. For the sake of disambiguation, we'll call this implementation `CheckF`:

```
import cats.Semigroup
import cats.syntax.either._    // for asLeft and asRight
import cats.syntax.semigroup._ // for |+|  
  
final case class CheckF[E, A](func: A => Either[E, A]) {  
  def apply(a: A): Either[E, A] =  
    func(a)  
  
  def and(that: CheckF[E, A])  
    (implicit s: Semigroup[E]): CheckF[E, A] =  
    CheckF { a =>  
      (this(a), that(a)) match {  
        case (Left(e1), Left(e2))  => (e1 |+| e2).asLeft  
        case (Left(e),  Right(_))  => e.asLeft  
        case (Right(_), Left(e))   => e.asLeft  
        case (Right(_), Right(_)) => a.asRight  
      }  
    }  
}
```

```
    }  
}
```

Let's test the behaviour we get. First we'll setup some checks:

```
import cats.instances.list._ // for Semigroup  
  
val a: CheckF[List[String], Int] =  
  CheckF { v =>  
    if(v > 2) v.asRight  
    else List("Must be > 2").asLeft  
  }  
  
val b: CheckF[List[String], Int] =  
  CheckF { v =>  
    if(v < -2) v.asRight  
    else List("Must be < -2").asLeft  
  }  
  
val check: CheckF[List[String], Int] =  
  a and b
```

Now run the check with some data:

```
check(5)  
// res5: Either[List[String], Int] = Left(value = List("Must be < -2"))  
//  
check(0)  
// res6: Either[List[String], Int] = Left(  
//   value = List("Must be > 2", "Must be < -2"))  
// )
```

Excellent! Everything works as expected! We're running both checks and accumulating errors as required.

What happens if we try to create checks that fail with a type that we can't accumulate? For example, there is no `Semigroup` instance for `Nothing`. What happens if we create instances of `CheckF[Nothing, A]`?

```
val a: CheckF[Nothing, Int] =
  CheckF(v => v.asRight)
```

```
val b: CheckF[Nothing, Int] =
  CheckF(v => v.asRight)
```

We can create checks just fine but when we come to combine them we get an error we might expect:

```
val check = a and b
// error:
// No given instance of type cats.kernel.Semigroup[Nothing] was found
// for parameter s of method and in class CheckF
// import cats.Semigroup
// ^
```

Now let's see another implementation strategy. In this approach we model checks as an algebraic data type, with an explicit data type for each combinator. We'll call this implementation Check:

```
sealed trait Check[E, A] {
  import Check._

  def and(that: Check[E, A]): Check[E, A] =
    And(this, that)

  def apply(a: A)(implicit s: Semigroup[E]): Either[E, A] =
    this match {
      case Pure(func) =>
        func(a)

      case And(left, right) =>
        (left(a), right(a)) match {
          case (Left(e1), Left(e2)) => (e1 |+| e2).asLeft
          case (Left(e), Right(_)) => e.asLeft
          case (Right(_), Left(e)) => e.asLeft
          case (Right(_), Right(_)) => a.asRight
        }
    }
}
```

```

object Check {
  final case class And[E, A](
    left: Check[E, A],
    right: Check[E, A]) extends Check[E, A]

  final case class Pure[E, A](
    func: A => Either[E, A]) extends Check[E, A]

  def pure[E, A](f: A => Either[E, A]): Check[E, A] =
    Pure(f)
}

```

Let's see an example:

```

val a: Check[List[String], Int] =
  Check.pure { v =>
    if(v > 2) v.asRight
    else List("Must be > 2").asLeft
  }

val b: Check[List[String], Int] =
  Check.pure { v =>
    if(v < -2) v.asRight
    else List("Must be < -2").asLeft
  }

val check: Check[List[String], Int] =
  a and b

```

While the ADT implementation is more verbose than the function wrapper implementation, it has the advantage of cleanly separating the structure of the computation (the ADT instance we create) from the process that gives it meaning (the apply method). From here we have a number of options:

- inspect and refactor checks after they are created;
- move the apply “interpreter” out into its own module;
- implement alternative interpreters providing other functionality (for example visualizing checks).

Because of its flexibility, we will use the ADT implementation for the rest of this case study.

[Return to the exercise](#)

K.4 Basic Combinators Part 4

The implementation of `apply` for `And` is using the pattern for applicative functors. Either has an Applicative instance, but it doesn't have the semantics we want. It fails fast instead of accumulating errors.

If we want to accumulate errors `Validated` is a more appropriate abstraction. As a bonus, we get more code reuse because we can lean on the applicative instance of `Validated` in the implementation of `apply`.

Here's the complete implementation:

```
import cats.Semigroup
import cats.data.Validated
import cats.syntax.apply._          // for mapN

sealed trait Check[E, A] {
  import Check._

  def and(that: Check[E, A]): Check[E, A] =
    And(this, that)

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, A] =
    this match {
      case Pure(func) =>
        func(a)

      case And(left, right) =>
        (left(a), right(a)).mapN((_, _) => a)
    }
}

object Check {
  final case class And[E, A](
    left: Check[E, A],
    right: Check[E, A]) extends Check[E, A]

  final case class Pure[E, A](
    func: A => Validated[E, A]) extends Check[E, A]
```

```
}
```

[Return to the exercise](#)

K.5 Basic Combinators Part 5

This reuses the same technique for `and`. We have to do a bit more work in the `apply` method. Note that it's OK to short-circuit in this case because the choice of rules is implicit in the semantics of "or".

```
import cats.Semigroup
import cats.data.Validated
import cats.syntax.semigroup._ // for |+
import cats.syntax.apply._    // for mapN
import cats.data.Validated._  // for Valid and Invalid

sealed trait Check[E, A] {
  import Check._

  def and(that: Check[E, A]): Check[E, A] =
    And(this, that)

  def or(that: Check[E, A]): Check[E, A] =
    Or(this, that)

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, A] =
    this match {
      case Pure(func) =>
        func(a)

      case And(left, right) =>
        (left(a), right(a)).mapN((_, _) => a)

      case Or(left, right) =>
        left(a) match {
          case Valid(a)    => Valid(a)
          case Invalid(e1) =>
            right(a) match {
              case Valid(a)    => Valid(a)
              case Invalid(e2) =>
```

```

        case Invalid(e2) => Invalid(e1 ++ e2)
    }
}
}

object Check {
  final case class And[E, A](
    left: Check[E, A],
    right: Check[E, A]) extends Check[E, A]

  final case class Or[E, A](
    left: Check[E, A],
    right: Check[E, A]) extends Check[E, A]

  final case class Pure[E, A](
    func: A => Validated[E, A]) extends Check[E, A]
}
}

```

[Return to the exercise](#)

K.6 Checks

If you follow the same strategy as `Predicate` you should be able to create code similar to the below:

```

import cats.Semigroup
import cats.data.Validated

sealed trait Check[E, A, B] {
  import Check._

  def apply(in: A)(implicit s: Semigroup[E]): Validated[E, B]

  def map[C](f: B => C): Check[E, A, C] =
    Map[E, A, B, C](this, f)
}

object Check {
  final case class Map[E, A, B, C](
    check: Check[E, A, B],
    f: B => C)
}

```

```
func: B => C) extends Check[E, A, C] {  
  
    def apply(in: A)(implicit s: Semigroup[E]): Validated[E, C] =  
        check(in).map(func)  
    }  
  
    final case class Pure[E, A](  
        pred: Predicate[E, A]) extends Check[E, A, A] {  
  
        def apply(in: A)(implicit s: Semigroup[E]): Validated[E, A] =  
            pred(in)  
        }  
  
        def apply[E, A](pred: Predicate[E, A]): Check[E, A, A] =  
            Pure(pred)  
    }  
}
```

[Return to the exercise](#)

K.7 Checks Part 2

It's the same implementation strategy as before with one wrinkle: `Validated` doesn't have a `flatMap` method. To implement `flatMap` we must momentarily switch to `Either` and then switch back to `Validated`. The `withEither` method on `Validated` does exactly this. From here we can just follow the types to implement `apply`.

```
import cats.Semigroup  
import cats.data.Validated  
  
sealed trait Check[E, A, B] {  
    def apply(in: A)(implicit s: Semigroup[E]): Validated[E, B]  
  
    def flatMap[C](f: B => Check[E, A, C]) =  
        FlatMap[E, A, B, C](this, f)  
  
    // other methods...
}
```

```

final case class FlatMap[E, A, B, C](
  check: Check[E, A, B],
  func: B => Check[E, A, C]) extends Check[E, A, C] {

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, C] =
    check(a).withEither(_.flatMap(b => func(b)(a).toEither))
}

// other data types...

```

[Return to the exercise](#)

K.8 Checks Part 3

Here's a minimal definition of `andThen` and its corresponding `AndThen` class:

```

sealed trait Check[E, A, B] {
  def apply(in: A)(implicit s: Semigroup[E]): Validated[E, B]

  def andThen[C](that: Check[E, B, C]): Check[E, A, C] =
    AndThen[E, A, B, C](this, that)
}

final case class AndThen[E, A, B, C](
  check1: Check[E, A, B],
  check2: Check[E, B, C]) extends Check[E, A, C] {

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, C] =
    check1(a).withEither(_.flatMap(b => check2(b).toEither))
}

```

[Return to the exercise](#)

K.9 Recap

Here's our final implementation, including some tidying and repackaging of the code:

```
import cats.Semigroup
import cats.data.Validated
import cats.data.Validated._ // for Valid and Invalid
import cats.syntax.semigroup._ // for |+|
import cats.syntax.apply._ // for mapN
import cats.syntax.validated._ // for valid and invalid
```

Here is our complete implementation of `Predicate`, including the `and` and `or` combinators and a `Predicate.apply` method to create a `Predicate` from a function:

```
sealed trait Predicate[E, A] {
  import Predicate._
  import Validated._

  def and(that: Predicate[E, A]): Predicate[E, A] =
    And(this, that)

  def or(that: Predicate[E, A]): Predicate[E, A] =
    Or(this, that)

  def apply(a: A)(implicit s: Semigroup[E]): Validated[E, A] =
    this match {
      case Pure(func) =>
        func(a)

      case And(left, right) =>
        (left(a), right(a)).mapN((_, _) => a)

      case Or(left, right) =>
        left(a) match {
          case Valid(_) => Valid(a)
          case Invalid(e1) =>
            right(a) match {
              case Valid(_) => Valid(a)
              case Invalid(e2) => Invalid(e1 |+| e2)
            }
        }
    }

  object Predicate {
```

```

final case class And[E, A](
  left: Predicate[E, A],
  right: Predicate[E, A]) extends Predicate[E, A]

final case class Or[E, A](
  left: Predicate[E, A],
  right: Predicate[E, A]) extends Predicate[E, A]

final case class Pure[E, A](
  func: A => Validated[E, A]) extends Predicate[E, A]

def apply[E, A](f: A => Validated[E, A]): Predicate[E, A] =
  Pure(f)

def lift[E, A](err: E, fn: A => Boolean): Predicate[E, A] =
  Pure(a => if(fn(a)) a.valid else err.invalid)
}

```

Here is a complete implementation of `Check`. Due to [a type inference bug](#) in Scala's pattern matching, we've switched to implementing `apply` using inheritance:

```

import cats.Semigroup
import cats.data.Validated
import cats.syntax.apply._          // for mapN
import cats.syntax.validated._     // for valid and invalid

sealed trait Check[E, A, B] {
  import Check._

  def apply(in: A)(implicit s: Semigroup[E]): Validated[E, B]

  def map[C](f: B => C): Check[E, A, C] =
    Map[E, A, B, C](this, f)

  def flatMap[C](f: B => Check[E, A, C]): Check[E, A, C] =
    FlatMap[E, A, B, C](this, f)

  def andThen[C](next: Check[E, B, C]): Check[E, A, C] =
    AndThen[E, A, B, C](this, next)
}

```

```
object Check {
  final case class Map[E, A, B, C](
    check: Check[E, A, B],
    func: B => C) extends Check[E, A, C] {

    def apply(a: A)
      (implicit s: Semigroup[E]): Validated[E, C] =
        check(a) map func
  }

  final case class FlatMap[E, A, B, C](
    check: Check[E, A, B],
    func: B => Check[E, A, C]) extends Check[E, A, C] {

    def apply(a: A)
      (implicit s: Semigroup[E]): Validated[E, C] =
        check(a).withEither(_.flatMap(b => func(b)(a).toEither))
  }

  final case class AndThen[E, A, B, C](
    check: Check[E, A, B],
    next: Check[E, B, C]) extends Check[E, A, C] {

    def apply(a: A)
      (implicit s: Semigroup[E]): Validated[E, C] =
        check(a).withEither(_.flatMap(b => next(b).toEither))
  }

  final case class Pure[E, A, B](
    func: A => Validated[E, B]) extends Check[E, A, B] {

    def apply(a: A)
      (implicit s: Semigroup[E]): Validated[E, B] =
        func(a)
  }

  final case class PurePredicate[E, A](
    pred: Predicate[E, A]) extends Check[E, A, A] {

    def apply(a: A)
      (implicit s: Semigroup[E]): Validated[E, A] =
        pred(a)
  }
}
```

```

def apply[E, A](pred: Predicate[E, A]): Check[E, A, A] =
  PurePredicate(pred)

def apply[E, A, B]
  (func: A => Validated[E, B]): Check[E, A, B] =
  Pure(func)
}

```

[Return to the exercise](#)

K.10 Recap Part 2

Here's our reference solution. Implementing this required more thought than we expected. Switching between `Check` and `Predicate` at appropriate places felt a bit like guesswork till we got the rule into our heads that `Predicate` doesn't transform its input. With this rule in mind things went fairly smoothly. In later sections we'll make some changes that make the library easier to use.

```

import cats.syntax.apply._      // for mapN
import cats.syntax.validated._ // for valid and invalid

```

Here's the implementation of `checkUsername`:

```

// A username must contain at least four characters
// and consist entirely of alphanumeric characters

val checkUsername: Check[Errors, String, String] =
  Check(longerThan(3) and alphanumeric)

```

And here's the implementation of `checkEmail`, built up from a number of smaller components:

```

// An email address must contain a single '@' sign.
// Split the string at the '@'.
// The string to the left must not be empty.
// The string to the right must be

```

```
// at least three characters long and contain a dot.

val splitEmail: Check[Errors, String, (String, String)] =
  Check(_.split('@') match {
    case Array(name, domain) =>
      (name, domain).validNel[String]
    case _ =>
      "Must contain a single @ character".
        invalidNel[(String, String)]
  })

val checkLeft: Check[Errors, String, String] =
  Check(longerThan(0))

val checkRight: Check[Errors, String, String] =
  Check(longerThan(3) and contains('.'))

val joinEmail: Check[Errors, (String, String), String] =
  Check { case (l, r) =>
    (checkLeft(l), checkRight(r)).mapN(_ + "@" + _)
  }

val checkEmail: Check[Errors, String, String] =
  splitEmail andThen joinEmail
```

Finally, here's a check for a User that depends on checkUsername and checkEmail:

```
final case class User(username: String, email: String)

def createUser(
  username: String,
  email: String): Validated[Errors, User] =
  (checkUsername(username), checkEmail(email)).mapN(User.apply)
```

We can check our work by creating a couple of example users:

```
createUser("Noel", "noel@underscore.io")
// res5: Validated[Errors, User] = Valid(
//   a = User(username = "Noel", email = "noel@underscore.io")
// )
```

```
createUser("", "dave@underscore.io@io")
// res6: Validated[Errors, User] = Invalid(
//   e = NonEmptyList(
//     head = "Must be longer than 3 characters",
//     tail = List("Must contain a single @ character")
//   )
// )
```

One distinct disadvantage of our example is that it doesn't tell us *where* the errors came from. We can either achieve that through judicious manipulation of error messages, or we can modify our library to track error locations as well as messages. Tracking error locations is outside the scope of this case study, so we'll leave this as an exercise to the reader.

K.11 Kleislis

Here's an abbreviated definition of `run`. Like `apply`, the method must accept an implicit `Semigroup`:

```
import cats.Semigroup
import cats.data.Validated

sealed trait Predicate[E, A] {
  def run(implicit s: Semigroup[E]): A => Either[E, A] =
    (a: A) => this(a).toEither

  def apply(a: A): Validated[E, A] =
    ??? // etc...

  // other methods...
}
```

[Return to the exercise](#)

K.12 Kleislis Part 2

Working around limitations of type inference can be quite frustrating when writing this code. Working out when to convert between Predicates, functions, and Validated, and Either simplifies things, but the process is still complex:

```
import cats.data.{Kleisli, NonEmptyList}
import cats.instances.either._    // for Semigroupal
```

Here is the preamble we suggested in the main text of the case study:

```
type Errors = NonEmptyList[String]

def error(s: String): NonEmptyList[String] =
  NonEmptyList(s, Nil)

type Result[A] = Either[Errors, A]

type Check[A, B] = Kleisli[Result, A, B]

def check[A, B](func: A => Result[B]): Check[A, B] =
  Kleisli(func)

def checkPred[A](pred: Predicate[Errors, A]): Check[A, A] =
  Kleisli[Result, A, A](pred.run)
```

Our base predicate definitions are essentially unchanged:

```
def longerThan(n: Int): Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must be longer than $n characters"),
    str => str.size > n)

val alphanumeric: Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must be all alphanumeric characters"),
    str => str.forall(_.isLetterOrDigit))

def contains(char: Char): Predicate[Errors, String] =
  Predicate.lift(
```

```

error(s"Must contain the character $char"),
str => str.contains(char))

def containsOnce(char: Char): Predicate[Errors, String] =
  Predicate.lift(
    error(s"Must contain the character $char only once"),
    str => str.filter(c => c == char).size == 1)

```

Our username and email examples are slightly different in that we make use of `check()` and `checkPred()` in different situations:

```

val checkUsername: Check[String, String] =
  checkPred(longerThan(3) and alphanumeric)

val splitEmail: Check[String, (String, String)] =
  check(_.split('@') match {
    case Array(name, domain) =>
      Right((name, domain))

    case _ =>
      Left(error("Must contain a single @ character"))
  })

val checkLeft: Check[String, String] =
  checkPred(longerThan(0))

val checkRight: Check[String, String] =
  checkPred(longerThan(3) and contains('.'))

val joinEmail: Check[(String, String), String] =
  check {
    case (l, r) =>
      (checkLeft(l), checkRight(r)).mapN(_ + "@" + _)
  }

val checkEmail: Check[String, String] =
  splitEmail andThen joinEmail

```

Finally, we can see that our `createUser` example works as expected using Kleisli:

```
final case class User(username: String, email: String)

def createUser(
    username: String,
    email: String): Either[Errors, User] = (
  checkUsername.run(username),
  checkEmail.run(email)
).mapN(User.apply)

createUser("Noel", "noel@underscore.io")
// res2: Either[Errors, User] = Right(
//   value = User(username = "Noel", email = "noel@underscore.io")
// )
createUser("", "dave@underscore.io@io")
// res3: Either[Errors, User] = Left(
//   value = NonEmptyList(head = "Must be longer than 3 characters",
//   tail = List())
// )
```

Appendix L

Solutions for: Case Study: CRDTs

L.1 GCounter Implementation

Hopefully the description above was clear enough that you can get to an implementation like the one below.

```
final case class GCounter(counters: Map[String, Int]) {
  def increment(machine: String, amount: Int) = {
    val value = amount + counters.getOrElse(machine, 0)
    GCounter(counters + (machine -> value))
  }

  def merge(that: GCounter): GCounter =
    GCounter(that.counters ++ this.counters.map {
      case (k, v) =>
        k -> (v max that.counters.getOrElse(k, 0))
    })

  def total: Int =
    counters.values.sum
}
```

[Return to the exercise](#)

L.2 BoundedSemiLattice Instances

It's common to place the instances in the companion object of `BoundedSemiLattice` so they are in the implicit scope without importing them.

Implementing the instance for `Set` provides good practice with implicit methods.

```
object wrapper {
    trait BoundedSemiLattice[A] extends CommutativeMonoid[A] {
        def combine(a1: A, a2: A): A
        def empty: A
    }

    object BoundedSemiLattice {
        implicit val intInstance: BoundedSemiLattice[Int] =
            new BoundedSemiLattice[Int] {
                def combine(a1: Int, a2: Int): Int =
                    a1 max a2

                val empty: Int =
                    0
            }

        implicit def setInstance[A]: BoundedSemiLattice[Set[A]] =
            new BoundedSemiLattice[Set[A]]{
                def combine(a1: Set[A], a2: Set[A]): Set[A] =
                    a1 union a2

                val empty: Set[A] =
                    Set.empty[A]
            }
    }
}; import wrapper._
```

[Return to the exercise](#)

L.3 Generic GCounter

Here's a working implementation. Note the use of `|+|` in the definition of `merge`, which significantly simplifies the process of merging and maximising counters:

```
import cats.instances.list._    // for Monoid
import cats.instances.map._    // for Monoid
import cats.syntax.semigroup._ // for |+|
import cats.syntax.foldable._  // for combineAll

final case class GCounter[A](counters: Map[String,A]) {
  def increment(machine: String, amount: A)
    (implicit m: CommutativeMonoid[A]): GCounter[A] = {
    val value = amount |+| counters.getOrElse(machine, m.empty)
    GCounter(counters + (machine -> value))
  }

  def merge(that: GCounter[A])
    (implicit b: BoundedSemiLattice[A]): GCounter[A] =
    GCounter(this.counters |+| that.counters)

  def total(implicit m: CommutativeMonoid[A]): A =
    this.counters.values.toList.combineAll
}
```

[Return to the exercise](#)

L.4 Abstracting GCounter to a Type Class

Here's the complete code for the instance. Write this definition in the companion object for `GCounter` to place it in global implicit scope:

```
import cats.instances.list._    // for Monoid
import cats.instances.map._    // for Monoid
import cats.syntax.semigroup._ // for |+|
import cats.syntax.foldable._  // for combineAll

implicit def mapGCounterInstance[K, V]: GCounter[Map, K, V] =
```

```

new GCounter[Map, K, V] {
    def increment(map: Map[K, V])(key: K, value: V)
        (implicit m: CommutativeMonoid[V]): Map[K, V] = {
        val total = map.getOrDefault(key, m.empty) |+| value
        map + (key -> total)
    }

    def merge(map1: Map[K, V], map2: Map[K, V])
        (implicit b: BoundedSemiLattice[V]): Map[K, V] =
        map1 |+| map2

    def total(map: Map[K, V])
        (implicit m: CommutativeMonoid[V]): V =
        map.values.toList.combineAll
    }
}

```

[Return to the exercise](#)

L.5 Abstracting a Key Value Store

Here's the code for the instance. Write the definition in the companion object for `KeyValueStore` to place it in global implicit scope:

```

implicit val mapKeyValueStoreInstance: KeyValueStore[Map] =
  new KeyValueStore[Map] {
    def put[K, V](f: Map[K, V])(k: K, v: V): Map[K, V] =
      f + (k -> v)

    def get[K, V](f: Map[K, V])(k: K): Option[V] =
      f.get(k)

    override def getOrElse[K, V](f: Map[K, V])
        (k: K, default: V): V =
      f.getOrElse(k, default)

    def values[K, V](f: Map[K, V]): List[V] =
      f.values.toList
  }
}

```
